260: (4)                """Provides an equitable coloring for nodes of `G`.
```

```
    Attempts to color a graph using `num_colors` colors, where no neighbors of
    a node can have same color as the node itself and the number of nodes with
    each color differ by at most 1. `num_colors` must be greater than the
    maximum degree of `G`. The algorithm is described in [1]_ and has
    complexity O(num_colors * n**2).
    Parameters
    ----------
    G : networkX graph
       The nodes of this graph will be colored.
    num_colors : number of colors to use
       This number must be at least one more than the maximum degree of nodes
       in the graph.
    Returns
    -------
    A dictionary with keys representing nodes and values representing
    corresponding coloring.
    Examples
    --------
    >>> G = nx.cycle_graph(4)
    >>> nx.coloring.equitable_color(G, num_colors=3)  # doctest: +SKIP
    {0: 2, 1: 1, 2: 2, 3: 0}
    Raises
    ------
    NetworkXAlgorithmError
        If `num_colors` is not at least the maximum degree of the graph `G`
    References

(4)                 Attempts to color a graph using as few colors as possible, where no
(4)                 neighbors of a node can have same color as the node itself. The
(4)                 given strategy determines the order in which nodes are colored.
(4)                 The strategies are described in [1]_, and smallest-last is based on
(4)                 [2]_.
```

```
    Parameters
    ----------
    G : NetworkX graph
    strategy : string or function(G, colors)
       A function (or a string representing a function) that provides
       the coloring strategy, by returning nodes in the ordering they
       should be colored. ``G`` is the graph, and ``colors`` is a
       dictionary of the currently assigned colors, keyed by nodes. The
       function must return an iterable over all the nodes in ``G``.
       If the strategy function is an iterator generator (that is, a
       function with ``yield`` statements), keep in mind that the
       ``colors`` dictionary will be updated after each ``yield``, since
       this function chooses colors greedily.
       If ``strategy`` is a string, it must be one of the following,
       each of which represents one of the built-in strategy functions.
       * ```'largest_first'```
       * ```'random_sequential'```
       * ```'smallest_last'```
       * ```'independent_set'```
       * ```'connected_sequential_bfs'```
       * ```'connected_sequential_dfs'```
       * ```'connected_sequential'``` (alias for the previous strategy)
       * ```'saturation_largest_first'```
       * ```'DSATUR'``` (alias for the previous strategy)
    interchange: bool
       Will use the color interchange algorithm described by [3]_ if set
       to ``True``.
       Note that ``saturation_largest_first`` and ``independent_set``
       do not work with interchange. Furthermore, if you use
       interchange with your own strategy function, you cannot rely
       on the values in the ``colors`` argument.
    Returns
    -------
    A dictionary with keys representing nodes and values representing
    corresponding coloring.
    Examples
    --------
    >>> G = nx.cycle_graph(4)
    >>> d = nx.coloring.greedy_color(G, strategy="largest_first")
    >>> d in [{0: 0, 1: 1, 2: 0, 3: 1}, {0: 1, 1: 0, 2: 1, 3: 0}]
    True
    Raises
    ------
    NetworkXPointlessConcept
        If ``strategy`` is ``saturation_largest_first`` or
        ``independent_set`` and ``interchange`` is ``True``.

14: (4)                 The asynchronous fluid communities algorithm is described in
15: (4)                 [1]_. The algorithm is based on the simple idea of fluids interacting
16: (4)                 in an environment, expanding and pushing each other. Its initialization is
17: (4)                 random, so found communities may vary on different executions.
18: (4)                 The algorithm proceeds as follows. First each of the initial k communities
19: (4)                 is initialized in a random vertex in the graph. Then the algorithm
iterates
20: (4)                 over all vertices in a random order, updating the community of each vertex
```

```
 21: (4)                 based on its own community and the communities of its neighbors. This
 22: (4)                 process is performed several times until convergence.
 23: (4)                 At all times, each community has a total density of 1, which is equally
 24: (4)                 distributed among the vertices it contains. If a vertex changes of
 25: (4)                 community, vertex densities of affected communities are adjusted
 26: (4)                 immediately. When a complete iteration over all vertices is done, such
that
 27: (4)                 no vertex changes the community it belongs to, the algorithm has converged
 28: (4)                 and returns.
 29: (4)                 This is the original version of the algorithm described in [1]_.
 30: (4)                 Unfortunately, it does not support weighted graphs yet.
 31: (4)                 Parameters
 32: (4)                 ----------
 33: (4)                 G : NetworkX graph
 34: (8)                     Graph must be simple and undirected.
 35: (4)                 k : integer
 36: (8)                     The number of communities to be found.
 37: (4)                 max_iter : integer
 38: (8)                     The number of maximum iterations allowed. By default 100.
 39: (4)                 seed : integer, random_state, or None (default)
 40: (8)                     Indicator of random number generation state.
 41: (8)                     See :ref:`Randomness<randomness>`.
 42: (4)                 Returns
 43: (4)                 -------
 44: (4)                 communities : iterable
 45: (8)                     Iterable of communities given as sets of nodes.
 46: (4)                 Notes
 47: (4)                 -----
 48: (4)                 k variable is not an optional argument.

7: (4)                  Parameters
8: (4)                  ----------
9: (4)                  G : NetworkX graph
10: (4)                 most_valuable_edge : function
11: (8)                     Function that takes a graph as input and outputs an edge. The
12: (8)                     edge returned by this function will be recomputed and removed at
13: (8)                     each iteration of the algorithm.
14: (8)                     If not specified, the edge with the highest
15: (8)                     :func:`networkx.edge_betweenness_centrality` will be used.
16: (4)                 Returns
17: (4)                 -------
18: (4)                 iterator
19: (8)                     Iterator over tuples of sets of nodes in `G`. Each set of node
20: (8)                     is a community, each tuple is a sequence of communities at a
21: (8)                     particular level of the algorithm.
22: (4)                 Examples
23: (4)                 --------
24: (4)                 To get the first pair of communities::
25: (8)                     >>> G = nx.path_graph(10)
26: (8)                     >>> comp = nx.community.girvan_newman(G)
27: (8)                     >>> tuple(sorted(c) for c in next(comp))
28: (8)                     ([0, 1, 2, 3, 4], [5, 6, 7, 8, 9])
29: (4)                 To get only the first *k* tuples of communities, use
```

```
 30: (4)                 :func:`itertools.islice`::
 31: (8)                     >>> import itertools
 32: (8)                     >>> G = nx.path_graph(8)
 33: (8)                     >>> k = 2
 34: (8)                     >>> comp = nx.community.girvan_newman(G)
 35: (8)                     >>> for communities in itertools.islice(comp, k):
 36: (8)                     ...     print(tuple(sorted(c) for c in communities))
 37: (8)                     ...
 38: (8)                     ([0, 1, 2, 3], [4, 5, 6, 7])
 39: (8)                     ([0, 1], [2, 3], [4, 5, 6, 7])
 40: (4)                 To stop getting tuples of communities once the number of communities
 41: (4)                 is greater than *k*, use :func:`itertools.takewhile`::
 42: (8)                     >>> import itertools
 43: (8)                     >>> G = nx.path_graph(8)
 44: (8)                     >>> k = 4
 45: (8)                     >>> comp = nx.community.girvan_newman(G)
 46: (8)                     >>> limited = itertools.takewhile(lambda c: len(c) <= k, comp)
 47: (8)                     >>> for communities in limited:
 48: (8)                     ...     print(tuple(sorted(c) for c in communities))
 49: (8)                     ...
 50: (8)                     ([0, 1, 2, 3], [4, 5, 6, 7])
 51: (8)                     ([0, 1], [2, 3], [4, 5, 6, 7])
 52: (8)                     ([0, 1], [2, 3], [4, 5], [6, 7])
 53: (4)                 To just choose an edge to remove based on the weight::
 54: (8)                     >>> from operator import itemgetter
 55: (8)                     >>> G = nx.path_graph(10)
 56: (8)                     >>> edges = G.edges()
 57: (8)                     >>> nx.set_edge_attributes(G, {(u, v): v for u, v in edges}, "weight")
 58: (8)                     >>> def heaviest(G):
 59: (8)                     ...     u, v, w = max(G.edges(data="weight"), key=itemgetter(2))
 60: (8)                     ...     return (u, v)
 61: (8)                     ...
 62: (8)                     >>> comp = nx.community.girvan_newman(G, most_valuable_edge=heaviest)
 63: (8)                     >>> tuple(sorted(c) for c in next(comp))
 64: (8)                     ([0, 1, 2, 3, 4, 5, 6, 7, 8], [9])
 65: (4)                 To utilize edge weights when choosing an edge with, for example, the
 66: (4)                 highest betweenness centrality::
 67: (8)                     >>> from networkx import edge_betweenness_centrality as betweenness
 68: (8)                     >>> def most_central_edge(G):
 69: (8)                     ...     centrality = betweenness(G, weight="weight")
 70: (8)                     ...     return max(centrality, key=centrality.get)
 71: (8)                     ...
 72: (8)                     >>> G = nx.path_graph(10)
 73: (8)                     >>> comp = nx.community.girvan_newman(G,
most_valuable_edge=most_central_edge)
 74: (8)                     >>> tuple(sorted(c) for c in next(comp))
 75: (8)                     ([0, 1, 2, 3, 4], [5, 6, 7, 8, 9])
 76: (4)                 To specify a different ranking algorithm for edges, use the
 77: (4)                 `most_valuable_edge` keyword argument::
 78: (8)                     >>> from networkx import edge_betweenness_centrality
 79: (8)                     >>> from random import random
 80: (8)                     >>> def most_central_edge(G):
 81: (8)                     ...     centrality = edge_betweenness_centrality(G)
 82: (8)                     ...     max_cent = max(centrality.values())
 83: (8)                     ...     # Scale the centrality values so they are between 0 and 1,
 84: (8)                     ...     # and add some random noise.
 85: (8)                     ...     centrality = {e: c / max_cent for e, c in centrality.items()}
 86: (8)                     ...     # Add some random noise.

```

```
edge.
    This algorithm works by calculating the edge betweenness for all
    edges and removing the edge with the highest value. It is then
    determined whether the graph has been broken into at least
    `number_of_sets` connected components.
    If not the process is repeated.
    Parameters
    ----------
    G : NetworkX Graph, DiGraph or MultiGraph
      Graph to be partitioned
    number_of_sets : int
      Number of sets in the desired partition of the graph
    weight : key, optional, default=None
      The key to use if using weights for edge betweenness calculation
    Returns
    -------
    C : list of sets
      Partition of the nodes of G
    Raises
    ------
    NetworkXError
      If number_of_sets is <= 0 or if number_of_sets > len(G)
    Examples
    --------
    >>> G = nx.karate_club_graph()
    >>> part = nx.community.edge_betweenness_partition(G, 2)
    >>> {0, 1, 3, 4, 5, 6, 7, 10, 11, 12, 13, 16, 17, 19, 21} in part
    True
    >>> {2, 8, 9, 14, 15, 18, 20, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32,
33} in part
    True
    See Also
    --------
    edge_current_flow_betweenness_partition
    Notes
    -----
    This algorithm is fairly slow, as both the calculation of connected
    components and edge betweenness relies on all pairs shortest
    path algorithms. They could potentially be combined to cut down
    on overall computation time.

39: (4)                 algorithm.
40: (4)                 This algorithm partitions a network into two sets by iteratively
41: (4)                 swapping pairs of nodes to reduce the edge cut between the two sets.  The
42: (4)                 pairs are chosen according to a modified form of Kernighan-Lin [1]_, which
43: (4)                 moves node individually, alternating between sides to keep the bisection
44: (4)                 balanced.
45: (4)                 Parameters
46: (4)                 ----------
47: (4)                 G : NetworkX graph
```

```
    Graph must be undirected.
partition : tuple
    Pair of iterables containing an initial partition. If not
    specified, a random balanced partition is used.
max_iter : int
    Maximum number of times to attempt swaps to find an
    improvement before giving up.
weight : key
    Edge data key to use as weight. If None, the weights are all
    set to one.
seed : integer, random_state, or None (default)
    Indicator of random number generation state.
    See :ref:`Randomness<randomness>`.
    Only used if partition is None
Returns
-------
partition : tuple
    A pair of sets of nodes representing the bipartition.
Raises
------
NetworkXError
    If partition is not a valid partition of the nodes of the graph.

14: (0)             def fast_label_propagation_communities(G, *, weight=None, seed=None):
15: (4)                 """Returns communities in `G` as detected by fast label propagation.
16: (4)                 The fast label propagation algorithm is described in [1]_. The algorithm
is
17: (4)                 probabilistic and the found communities may vary in different executions.
18: (4)                 The algorithm operates as follows. First, the community label of each node
is
19: (4)                 set to a unique label. The algorithm then repeatedly updates the labels of
20: (4)                 the nodes to the most frequent label in their neighborhood. In case of
ties,
21: (4)                 a random label is chosen from the most frequent labels.
22: (4)                 The algorithm maintains a queue of nodes that still need to be processed.
23: (4)                 Initially, all nodes are added to the queue in a random order. Then the
nodes
24: (4)                 are removed from the queue one by one and processed. If a node updates its
label,
25: (4)                 all its neighbors that have a different label are added to the queue (if
not
26: (4)                 already in the queue). The algorithm stops when the queue is empty.
27: (4)                 Parameters
28: (4)                 ----------
29: (4)                 G : Graph, DiGraph, MultiGraph, or MultiDiGraph
30: (8)                     Any NetworkX graph.
31: (4)                 weight : string, or None (default)
32: (8)                     The edge attribute representing a non-negative weight of an edge. If
None,
33: (8)                     each edge is assumed to have weight one. The weight of an edge is used
in
34: (8)                     determining the frequency with which a label appears among the
neighbors of
35: (8)                     a node (edge with weight `w` is equivalent to `w` unweighted edges).
36: (4)                 seed : integer, random_state, or None (default)
37: (8)                     Indicator of random number generation state. See

14: (4)                 r"""Find the best partition of a graph using the Louvain Community
Detection
15: (4)                 Algorithm.
16: (4)                 Louvain Community Detection Algorithm is a simple method to extract the
community
17: (4)                 structure of a network. This is a heuristic method based on modularity
optimization. [1]_
18: (4)                 The algorithm works in 2 steps. On the first step it assigns every node to
be
19: (4)                 in its own community and then for each node it tries to find the maximum
positive
20: (4)                 modularity gain by moving each node to all of its neighbor communities. If
no positive
21: (4)                 gain is achieved the node remains in its original community.
22: (4)                 The modularity gain obtained by moving an isolated node $i$ into a
community $C$ can
23: (4)                 easily be calculated by the following formula (combining [1]_ [2]_ and
some algebra):
24: (4)                 .. math::
25: (8)                     \Delta Q = \frac{k_{i,in}}{2m} - \gamma\frac{ \Sigma_{tot} \cdot k_i}
{2m^2}
26: (4)                 where $m$ is the size of the graph, $k_{i,in}$ is the sum of the weights
of the links
27: (4)                 from $i$ to nodes in $C$, $k_i$ is the sum of the weights of the links
incident to node $i$,
28: (4)                 $\Sigma_{tot}$ is the sum of the weights of the links incident to nodes in
$C$ and $\gamma$
29: (4)                 is the resolution parameter.
30: (4)                 For the directed case the modularity gain can be computed using this
formula according to [3]_
31: (4)                 .. math::
32: (8)                     \Delta Q = \frac{k_{i,in}}{m}
33: (8)                     - \gamma\frac{k_i^{out} \cdot\Sigma_{tot}^{in} + k_i^{in} \cdot
\Sigma_{tot}^{out}}{m^2}
34: (4)                 where $k_i^{out}$, $k_i^{in}$ are the outer and inner weighted degrees of
node $i$ and
35: (4)                 $\Sigma_{tot}^{in}$, $\Sigma_{tot}^{out}$ are the sum of in-going and out-
going links incident
36: (4)                 to nodes in $C$.
37: (4)                 The first phase continues until no individual move can improve the
modularity.
38: (4)                 The second phase consists in building a new network whose nodes are now
the communities
```

```
39: (4)                 found in the first phase. To do so, the weights of the links between the
new nodes are given by
40: (4)                 the sum of the weight of the links between nodes in the corresponding two
communities. Once this
41: (4)                 phase is complete it is possible to reapply the first phase creating
bigger communities with
42: (4)                 increased modularity.
43: (4)                 The above two phases are executed until no modularity gain is achieved (or
is less than
44: (4)                 the `threshold`, or until `max_levels` is reached).
45: (4)                 Be careful with self-loops in the input graph. These are treated as
46: (4)                 previously reduced communities -- as if the process had been started
47: (4)                 in the middle of the algorithm. Large self-loop edge weights thus
48: (4)                 represent strong communities and in practice may be hard to add
49: (4)                 other nodes to.  If your input graph edge weights for self-loops
50: (4)                 do not represent already reduced communities you may want to remove
51: (4)                 the self-loops before inputting that graph.
52: (4)                 Parameters
53: (4)                 ----------
54: (4)                 G : NetworkX graph
55: (4)                 weight : string or None, optional (default="weight")
56: (8)                     The name of an edge attribute that holds the numerical value
57: (8)                     used as a weight. If None then each edge has weight 1.
58: (4)                 resolution : float, optional (default=1)
59: (8)                     If resolution is less than 1, the algorithm favors larger communities.
60: (8)                     Greater than 1 favors smaller communities
61: (4)                 threshold : float, optional (default=0.0000001)
62: (8)                     Modularity gain threshold for each level. If the gain of modularity
63: (8)                     between 2 levels of the algorithm is less than the given threshold
64: (8)                     then the algorithm stops and returns the resulting communities.
65: (4)                 max_level : int or None, optional (default=None)
66: (8)                     The maximum number of levels (steps of the algorithm) to compute.
67: (8)                     Must be a positive integer or None. If None, then there is no max
68: (8)                     level and the threshold parameter determines the stopping condition.

70: (8)                     Indicator of random number generation state.
71: (8)                     See :ref:`Randomness<randomness>`.
72: (4)                 Returns
73: (4)                 -------
74: (4)                 list
75: (8)                     A list of sets (partition of `G`). Each set represents one community
and contains
76: (8)                     all the nodes that constitute it.
77: (4)                 Examples
78: (4)                 --------
79: (4)                 >>> import networkx as nx
80: (4)                 >>> G = nx.petersen_graph()
81: (4)                 >>> nx.community.louvain_communities(G, seed=123)
82: (4)                 [{0, 4, 5, 7, 9}, {1, 2, 3, 6, 8}]
83: (4)                 Notes
84: (4)                 -----
85: (4)                 The order in which the nodes are considered can affect the final output.
In the algorithm
86: (4)                 the ordering happens using a random shuffle.

```

```
@nx._dispatchable(edge_attrs="weight")
def modularity(G, communities, weight="weight", resolution=1):
    r"""Returns the modularity of the given partition of the graph.
    Modularity is defined in [1]_ as
    .. math::
        Q = \frac{1}{2m} \sum_{ij} \left( A_{ij} - \gamma\frac{k_ik_j}{2m}\right)
            \delta(c_i,c_j)
    where $m$ is the number of edges (or sum of all edge weights as in [5]_),
    $A$ is the adjacency matrix of `G`, $k_i$ is the (weighted) degree of $i$,
    $\gamma$ is the resolution parameter, and $\delta(c_i, c_j)$ is 1 if $i$ and
    $j$ are in the same community else 0.
    According to [2]_ (and verified by some algebra) this can be reduced to
    .. math::
       Q = \sum_{c=1}^{n}
       \left[ \frac{L_c}{m} - \gamma\left( \frac{k_c}{2m} \right) ^2 \right]
    where the sum iterates over all communities $c$, $m$ is the number of edges,
    $L_c$ is the number of intra-community links for community $c$,
    $k_c$ is the sum of degrees of the nodes in community $c$,
    and $\gamma$ is the resolution parameter.
    The resolution parameter sets an arbitrary tradeoff between intra-group
    edges and inter-group edges. More complex grouping patterns can be
    discovered by analyzing the same network with multiple values of gamma
    and then combining the results [3]_. That said, it is very common to
    simply use gamma=1. More on the choice of gamma is in [4]_.
    The second formula is the one actually used in calculation of the modularity.
    For directed graphs the second formula replaces $k_c$ with $k^{in}_c k^{out}_c$.
    Parameters
    ----------
    G : NetworkX Graph
    communities : list or iterable of set of nodes
        These node sets must represent a partition of G's nodes.
    weight : string or None, optional (default="weight")
        The edge attribute that holds the numerical value used
        as a weight. If None or an edge does not have that attribute,
        then that edge has weight 1.
    resolution : float (default=1)
        If resolution is less than 1, modularity favors larger communities.
        Greater than 1 favors smaller communities.
    Returns
    -------
    Q : float
        The modularity of the partition.
    Raises
    ------
    NotAPartition
        If `communities` is not a partition of the nodes of `G`.
    Examples
    --------
    >>> G = nx.barbell_graph(3, 0)
    >>> nx.community.modularity(G, [{0, 1, 2}, {3, 4, 5}])
    0.35714285714285715
    >>> nx.community.modularity(G, nx.community.label_propagation_communities(G))
    0.35714285714285715

(4)                 r"""Find communities in G using greedy modularity maximization.
(4)                 This function uses Clauset-Newman-Moore greedy modularity maximization [2]_
(4)                 to find the community partition with the largest modularity.
(4)                 Greedy modularity maximization begins with each node in its own community
(4)                 and repeatedly joins the pair of communities that lead to the largest
(4)                 modularity until no further increase in modularity is possible (a maximum).
(4)                 Two keyword arguments adjust the stopping condition. `cutoff` is a lower
(4)                 limit on the number of communities so you can stop the process before
(4)                 reaching a maximum (used to save computation time). `best_n` is an upper
(4)                 limit on the number of communities so you can make the process continue
(4)                 until at most n communities remain even if the maximum modularity occurs
(4)                 for more. To obtain exactly n communities, set both `cutoff` and `best_n` to n.
(4)                 This function maximizes the generalized modularity, where `resolution`
(4)                 is the resolution parameter, often expressed as $\gamma$.
(4)                 See :func:`~networkx.algorithms.community.quality.modularity`.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(4)                 weight : string or None, optional (default=None)
(8)                     The name of an edge attribute that holds the numerical value used
(8)                     as a weight.  If None, then each edge has weight 1.
(8)                     The degree is the sum of the edge weights adjacent to the node.
(4)                 resolution : float, optional (default=1)
(8)                     If resolution is less than 1, modularity favors larger communities.
(8)                     Greater than 1 favors smaller communities.
(4)                 cutoff : int, optional (default=1)
(8)                     A minimum number of communities below which the merging process stops.
(8)                     The process stops at this number of communities even if modularity
(8)                     is not maximized. The goal is to let the user stop the process early.
(8)                     The process stops before the cutoff if it finds a maximum of modularity.
(4)                 best_n : int or None, optional (default=None)
(8)                     A maximum number of communities above which the merging process will
(8)                     not stop. This forces community merging to continue after modularity
(8)                     starts to decrease until `best_n` communities remain.
(8)                     If ``None``, don't force it to continue beyond a maximum.
(4)                 Raises
(4)                 ------
(4)                 ValueError : If the `cutoff` or `best_n`  value is not in the range
(8)                     ``[1, G.number_of_nodes()]``, or if `best_n` < `cutoff`.
(4)                 Returns
(4)                 -------
(4)                 communities: list
(8)                     A list of frozensets of nodes, one for each community.
(8)                     Sorted by length with largest communities first.
(4)                 Examples
(4)                 --------

49: (4)                 Notes
50: (4)                 -----
51: (4)                 The algorithm to find articulation points and biconnected
52: (4)                 components is implemented using a non-recursive depth-first-search
53: (4)                 (DFS) that keeps track of the highest level that back edges reach
54: (4)                 in the DFS tree.  A node `n` is an articulation point if, and only
55: (4)                 if, there exists a subtree rooted at `n` such that there is no
56: (4)                 back edge from any successor of `n` that links to a predecessor of
57: (4)                 `n` in the DFS tree.  By keeping track of all the edges traversed
58: (4)                 by the DFS we can obtain the biconnected components because all
59: (4)                 edges of a bicomponent will be traversed consecutively between
60: (4)                 articulation points.
61: (4)                 References
62: (4)                 ----------

140: (0)            @nx._dispatchable
141: (0)            def biconnected_components(G):
142: (4)                """Returns a generator of sets of nodes, one set for each biconnected
143: (4)                component of the graph
```

```
    Biconnected components are maximal subgraphs such that the removal of a
    node (and all edges incident on that node) will not disconnect the
    subgraph. Note that nodes may be part of more than one biconnected
    component.  Those nodes are articulation points, or cut vertices.  The
    removal of articulation points will increase the number of connected
    components of the graph.
    Notice that by convention a dyad is considered a biconnected component.
    Parameters
    ----------
    G : NetworkX Graph
        An undirected graph.
    Returns
    -------
    nodes : generator
        Generator of sets of nodes, one set for each biconnected component.
    Raises
    ------
    NetworkXNotImplemented
        If the input graph is not undirected.
    Examples
    --------
    >>> G = nx.lollipop_graph(5, 1)
    >>> print(nx.is_biconnected(G))
    False
    >>> bicomponents = list(nx.biconnected_components(G))
    >>> len(bicomponents)
    2
    >>> G.add_edge(0, 5)
    >>> print(nx.is_biconnected(G))
    True
    >>> bicomponents = list(nx.biconnected_components(G))
    >>> len(bicomponents)
    1
    You can generate a sorted list of biconnected components, largest
    first, using sort.
    >>> G.remove_edge(0, 5)
    >>> [len(c) for c in sorted(nx.biconnected_components(G), key=len, reverse=True)]
    [5, 2]
    If you only want the largest connected component, it's more
    efficient to use max instead of sort.
    >>> Gc = max(nx.biconnected_components(G), key=len)
    To create the components as subgraphs use:
    ``(G.subgraph(c).copy() for c in biconnected_components(G))``
    See Also
    --------
    is_biconnected
    articulation_points
    biconnected_component_edges
    k_components : this function is a special case where k=2
    bridge_components : similar to this function, but is defined using
        2-edge-connectivity instead of 2-node-connectivity.
    Notes
    -----
    The algorithm to find articulation points and biconnected
    components is implemented using a non-recursive depth-first-search
    (DFS) that keeps track of the highest level that back edges reach
    in the DFS tree.  A node `n` is an articulation point if, and only
    if, there exists a subtree rooted at `n` such that there is no
    back edge from any successor of `n` that links to a predecessor of
    `n` in the DFS tree.  By keeping track of all the edges traversed
    by the DFS we can obtain the biconnected components because all
    edges of a bicomponent will be traversed consecutively between
    articulation points.

8: (4)                  r"""Returns True if the graph is semiconnected, False otherwise.
9: (4)                  A graph is semiconnected if and only if for any pair of nodes, either one
10: (4)                 is reachable from the other, or they are mutually reachable.
11: (4)                 This function uses a theorem that states that a DAG is semiconnected
12: (4)                 if for any topological sort, for node $v_n$ in that sort, there is an
13: (4)                 edge $(v_i, v_{i+1})$. That allows us to check if a non-DAG `G` is
14: (4)                 semiconnected by condensing the graph: i.e. constructing a new graph `H`
15: (4)                 with nodes being the strongly connected components of `G`, and edges
16: (4)                 (scc_1, scc_2) if there is a edge $(v_1, v_2)$ in `G` for some
17: (4)                 $v_1 \in scc_1$ and $v_2 \in scc_2$. That results in a DAG, so we compute
18: (4)                 the topological sort of `H` and check if for every $n$ there is an edge
19: (4)                 $(scc_n, scc_{n+1})$.

28: (4)                 r"""Computes local node connectivity for nodes s and t.
29: (4)                 Local node connectivity for two non adjacent nodes s and t is the
30: (4)                 minimum number of nodes that must be removed (along with their incident
31: (4)                 edges) to disconnect them.
32: (4)                 This is a flow based implementation of node connectivity. We compute the
33: (4)                 maximum flow on an auxiliary digraph build from the original input
34: (4)                 graph (see below for details).
```

```
 35: (4)                 Parameters
 36: (4)                 ----------
 37: (4)                 G : NetworkX graph
 38: (8)                     Undirected graph
 39: (4)                 s : node
 40: (8)                     Source node
 41: (4)                 t : node
 42: (8)                     Target node
 43: (4)                 flow_func : function
 44: (8)                     A function for computing the maximum flow among a pair of nodes.
 45: (8)                     The function has to accept at least three parameters: a Digraph,
 46: (8)                     a source node, and a target node. And return a residual network
 47: (8)                     that follows NetworkX conventions (see :meth:`maximum_flow` for
 48: (8)                     details). If flow_func is None, the default maximum flow function
 49: (8)                     (:meth:`edmonds_karp`) is used. See below for details. The choice
 50: (8)                     of the default function may change from version to version and
 51: (8)                     should not be relied on. Default value: None.
 52: (4)                 auxiliary : NetworkX DiGraph
 53: (8)                     Auxiliary digraph to compute flow based node connectivity. It has
 54: (8)                     to have a graph attribute called mapping with a dictionary mapping
 55: (8)                     node names in G and in the auxiliary digraph. If provided
 56: (8)                     it will be reused instead of recreated. Default value: None.
 57: (4)                 residual : NetworkX DiGraph
 58: (8)                     Residual network to compute maximum flow. If provided it will be
 59: (8)                     reused instead of recreated. Default value: None.
 60: (4)                 cutoff : integer, float, or None (default: None)
 61: (8)                     If specified, the maximum flow algorithm will terminate when the
 62: (8)                     flow value reaches or exceeds the cutoff. This only works for flows
 63: (8)                     that support the cutoff parameter (most do) and is ignored otherwise.
 64: (4)                 Returns
 65: (4)                 -------
 66: (4)                 K : integer
 67: (8)                     local node connectivity for nodes s and t
 68: (4)                 Examples
 69: (4)                 --------
 70: (4)                 This function is not imported in the base NetworkX namespace, so you
 71: (4)                 have to explicitly import it from the connectivity package:
 72: (4)                 >>> from networkx.algorithms.connectivity import local_node_connectivity
 73: (4)                 We use in this example the platonic icosahedral graph, which has node
 74: (4)                 connectivity 5.
 75: (4)                 >>> G = nx.icosahedral_graph()
 76: (4)                 >>> local_node_connectivity(G, 0, 6)
 77: (4)                 5
 78: (4)                 If you need to compute local connectivity on several pairs of
 79: (4)                 nodes in the same graph, it is recommended that you reuse the
 80: (4)                 data structures that NetworkX uses in the computation: the
 81: (4)                 auxiliary digraph for node connectivity, and the residual
 82: (4)                 network for the underlying maximum flow computation.
 83: (4)                 Example of how to compute local node connectivity among
 84: (4)                 all pairs of nodes of the platonic icosahedral graph reusing
 85: (4)                 the data structures.
 86: (4)                 >>> import itertools
 87: (4)                 >>> # You also have to explicitly import the function for
 88: (4)                 >>> # building the auxiliary digraph from the connectivity package
 89: (4)                 >>> from networkx.algorithms.connectivity import
build_auxiliary_node_connectivity
 90: (4)                 >>> H = build_auxiliary_node_connectivity(G)
 91: (4)                 >>> # And the function for building the residual network from the
 92: (4)                 >>> # flow package
 93: (4)                 >>> from networkx.algorithms.flow import build_residual_network
 94: (4)                 >>> # Note that the auxiliary digraph has an edge attribute named capacity
 95: (4)                 >>> R = build_residual_network(H, "capacity")
 96: (4)                 >>> result = dict.fromkeys(G, dict())
 97: (4)                 >>> # Reuse the auxiliary digraph and the residual network by passing them
 98: (4)                 >>> # as parameters
 99: (4)                 >>> for u, v in itertools.combinations(G, 2):
100: (4)                 ...     k = local_node_connectivity(G, u, v, auxiliary=H, residual=R)
101: (4)                 ...     result[u][v] = k
102: (4)                 >>> all(result[u][v] == 5 for u, v in itertools.combinations(G, 2))
```

```
(4)                 True
(4)                 You can also use alternative flow algorithms for computing node
(4)                 connectivity. For instance, in dense networks the algorithm
(4)                 :meth:`shortest_augmenting_path` will usually perform better than
(4)                 the default :meth:`edmonds_karp` which is faster for sparse
(4)                 networks with highly skewed degree distributions. Alternative flow
(4)                 functions have to be explicitly imported from the flow package.
(4)                 >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)                 >>> local_node_connectivity(G, 0, 6, flow_func=shortest_augmenting_path)
(4)                 5
(4)                 Notes
(4)                 -----
(4)                 This is a flow based implementation of node connectivity. We compute the
(4)                 maximum flow using, by default, the :meth:`edmonds_karp` algorithm (see:
(4)                 :meth:`maximum_flow`) on an auxiliary digraph build from the original
(4)                 input graph:
(4)                 For an undirected graph G having `n` nodes and `m` edges we derive a
(4)                 directed graph H with `2n` nodes and `2m+n` arcs by replacing each
(4)                 original node `v` with two nodes `v_A`, `v_B` linked by an (internal)
(4)                 arc in H. Then for each edge (`u`, `v`) in G we add two arcs
(4)                 (`u_B`, `v_A`) and (`v_B`, `u_A`) in H. Finally we set the attribute
(4)                 capacity = 1 for each arc in H [1]_ .
(4)                 For a directed graph G having `n` nodes and `m` arcs we derive a
(4)                 directed graph H with `2n` nodes and `m+n` arcs by replacing each
(4)                 original node `v` with two nodes `v_A`, `v_B` linked by an (internal)
(4)                 arc (`v_A`, `v_B`) in H. Then for each arc (`u`, `v`) in G we add one arc
(4)                 (`u_B`, `v_A`) in H. Finally we set the attribute capacity = 1 for
(4)                 each arc in H.
(4)                 This is equal to the local node connectivity because the value of
(4)                 a maximum s-t-flow is equal to the capacity of a minimum s-t-cut.

```

```
(0)            def node_connectivity(G, s=None, t=None, flow_func=None):
(4)                r"""Returns node connectivity for a graph or digraph G.
(4)                Node connectivity is equal to the minimum number of nodes that
(4)                must be removed to disconnect G or render it trivial. If source
(4)                and target nodes are provided, this function returns the local node
(4)                connectivity: the minimum number of nodes that must be removed to break
(4)                all paths from source to target in G.
(4)                Parameters
(4)                ----------
(4)                G : NetworkX graph
(8)                    Undirected graph
(4)                s : node
(8)                    Source node. Optional. Default value: None.
(4)                t : node
(8)                    Target node. Optional. Default value: None.
(4)                flow_func : function
(8)                    A function for computing the maximum flow among a pair of nodes.
(8)                    The function has to accept at least three parameters: a Digraph,
(8)                    a source node, and a target node. And return a residual network
(8)                    that follows NetworkX conventions (see :meth:`maximum_flow` for
(8)                    details). If flow_func is None, the default maximum flow function
(8)                    (:meth:`edmonds_karp`) is used. See below for details. The
(8)                    choice of the default function may change from version
(8)                    to version and should not be relied on. Default value: None.
(4)                Returns
(4)                -------
(4)                K : integer
(8)                    Node connectivity of G, or local node connectivity if source
(8)                    and target are provided.
(4)                Examples
(4)                --------
(4)                >>> # Platonic icosahedral graph is 5-node-connected
(4)                >>> G = nx.icosahedral_graph()
(4)                >>> nx.node_connectivity(G)
(4)                5
(4)                You can use alternative flow algorithms for the underlying maximum
(4)                flow computation. In dense networks the algorithm
(4)                :meth:`shortest_augmenting_path` will usually perform better
(4)                than the default :meth:`edmonds_karp`, which is faster for
(4)                sparse networks with highly skewed degree distributions. Alternative
(4)                flow functions have to be explicitly imported from the flow package.
(4)                >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)                >>> nx.node_connectivity(G, flow_func=shortest_augmenting_path)
(4)                5
(4)                If you specify a pair of nodes (source and target) as parameters,
(4)                this function returns the value of local node connectivity.
(4)                >>> nx.node_connectivity(G, 3, 7)
(4)                5
(4)                If you need to perform several local computations among different
(4)                pairs of nodes on the same graph, it is recommended that you reuse
(4)                the data structures used in the maximum flow computations. See
(4)                :meth:`local_node_connectivity` for details.
(4)                Notes
(4)                -----
(4)                This is a flow based implementation of node connectivity. The
(4)                algorithm works by solving $O((n-\delta-1+\delta(\delta-1)/2))$
(4)                maximum flow problems on an auxiliary digraph. Where $\delta$
(4)                is the minimum degree of G. For details about the auxiliary
(4)                digraph and the computation of local node connectivity see
(4)                :meth:`local_node_connectivity`. This implementation is based
(4)                on algorithm 11 in [1]_.

(0)  def local_edge_connectivity(
(4)     G, s, t, flow_func=None, auxiliary=None, residual=None, cutoff=None
(0)  ):
(4)     r"""Returns local edge connectivity for nodes s and t in G.
(4)     Local edge connectivity for two nodes s and t is the minimum number
(4)     of edges that must be removed to disconnect them.
(4)     This is a flow based implementation of edge connectivity. We compute the
(4)     maximum flow on an auxiliary digraph build from the original
(4)     network (see below for details). This is equal to the local edge
(4)     connectivity because the value of a maximum s-t-flow is equal to the
(4)     capacity of a minimum s-t-cut (Ford and Fulkerson theorem) [1]_ .
(4)     Parameters
(4)     ----------
(4)     G : NetworkX graph
(8)         Undirected or directed graph
(4)     s : node
(8)         Source node
(4)     t : node
(8)         Target node
(4)     flow_func : function
(8)         A function for computing the maximum flow among a pair of nodes.
(8)         The function has to accept at least three parameters: a Digraph,
(8)         a source node, and a target node. And return a residual network
(8)         that follows NetworkX conventions (see :meth:`maximum_flow` for
(8)         details). If flow_func is None, the default maximum flow function
(8)         (:meth:`edmonds_karp`) is used. See below for details. The
(8)         choice of the default function may change from version
(8)         to version and should not be relied on. Default value: None.
(4)     auxiliary : NetworkX DiGraph
(8)         Auxiliary digraph for computing flow based edge connectivity. If
(8)         provided it will be reused instead of recreated. Default value: None.
(4)     residual : NetworkX DiGraph
(8)         Residual network to compute maximum flow. If provided it will be
(8)         reused instead of recreated. Default value: None.
(4)     cutoff : integer, float, or None (default: None)
(8)         If specified, the maximum flow algorithm will terminate when the
(8)         flow value reaches or exceeds the cutoff. This only works for flows
(8)         that support the cutoff parameter (most do) and is ignored otherwise.
(4)     Returns
(4)     -------
(4)     K : integer
(8)         local edge connectivity for nodes s and t.
(4)     Examples
(4)     --------
(4)     This function is not imported in the base NetworkX namespace, so you
(4)     have to explicitly import it from the connectivity package:
(4)     >>> from networkx.algorithms.connectivity import local_edge_connectivity
(4)     We use in this example the platonic icosahedral graph, which has edge
(4)     connectivity 5.
(4)     >>> G = nx.icosahedral_graph()
(4)     >>> local_edge_connectivity(G, 0, 6)
(4)     5
(4)     If you need to compute local connectivity on several pairs of
(4)     nodes in the same graph, it is recommended that you reuse the
(4)     data structures that NetworkX uses in the computation: the
(4)     auxiliary digraph for edge connectivity, and the residual
(4)     network for the underlying maximum flow computation.
(4)     Example of how to compute local edge connectivity among
(4)     all pairs of nodes of the platonic icosahedral graph reusing
(4)     the data structures.
(4)     >>> import itertools
```

```
(4)                 >>> # You also have to explicitly import the function for
(4)                 >>> # building the auxiliary digraph from the connectivity package
(4)                 >>> from networkx.algorithms.connectivity import
build_auxiliary_edge_connectivity
(4)                 >>> H = build_auxiliary_edge_connectivity(G)
(4)                 >>> # And the function for building the residual network from the
(4)                 >>> # flow package
(4)                 >>> from networkx.algorithms.flow import build_residual_network
(4)                 >>> # Note that the auxiliary digraph has an edge attribute named capacity
(4)                 >>> R = build_residual_network(H, "capacity")
(4)                 >>> result = dict.fromkeys(G, dict())
(4)                 >>> # Reuse the auxiliary digraph and the residual network by passing them
(4)                 >>> # as parameters
(4)                 >>> for u, v in itertools.combinations(G, 2):
(4)                 ...     k = local_edge_connectivity(G, u, v, auxiliary=H, residual=R)
(4)                 ...     result[u][v] = k
(4)                 >>> all(result[u][v] == 5 for u, v in itertools.combinations(G, 2))
(4)                 True
(4)                 You can also use alternative flow algorithms for computing edge
(4)                 connectivity. For instance, in dense networks the algorithm
(4)                 :meth:`shortest_augmenting_path` will usually perform better than
(4)                 the default :meth:`edmonds_karp` which is faster for sparse
(4)                 networks with highly skewed degree distributions. Alternative flow
(4)                 functions have to be explicitly imported from the flow package.
(4)                 >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)                 >>> local_edge_connectivity(G, 0, 6, flow_func=shortest_augmenting_path)
(4)                 5
(4)                 Notes
(4)                 -----
(4)                 This is a flow based implementation of edge connectivity. We compute the
(4)                 maximum flow using, by default, the :meth:`edmonds_karp` algorithm on an
(4)                 auxiliary digraph build from the original input graph:
(4)                 If the input graph is undirected, we replace each edge (`u`,`v`) with
(4)                 two reciprocal arcs (`u`, `v`) and (`v`, `u`) and then we set the
attribute
(4)                 'capacity' for each arc to 1. If the input graph is directed we simply
(4)                 add the 'capacity' attribute. This is an implementation of algorithm 1
(4)                 in [1]_.
(4)                 The maximum flow in the auxiliary network is equal to the local edge
(4)                 connectivity because the value of a maximum s-t-flow is equal to the
(4)                 capacity of a minimum s-t-cut (Ford and Fulkerson theorem).

(4)         r"""Returns the edge connectivity of the graph or digraph G.
(4)         The edge connectivity is equal to the minimum number of edges that
(4)         must be removed to disconnect G or render it trivial. If source
(4)         and target nodes are provided, this function returns the local edge
(4)         connectivity: the minimum number of edges that must be removed to
(4)         break all paths from source to target in G.
(4)         Parameters
(4)         ----------
(4)         G : NetworkX graph
(8)             Undirected or directed graph
(4)         s : node
(8)             Source node. Optional. Default value: None.
(4)         t : node
(8)             Target node. Optional. Default value: None.
(4)         flow_func : function
(8)             A function for computing the maximum flow among a pair of nodes.
(8)             The function has to accept at least three parameters: a Digraph,
(8)             a source node, and a target node. And return a residual network
(8)             that follows NetworkX conventions (see :meth:`maximum_flow` for
(8)             details). If flow_func is None, the default maximum flow function
(8)             (:meth:`edmonds_karp`) is used. See below for details. The
(8)             choice of the default function may change from version
(8)             to version and should not be relied on. Default value: None.
(4)         cutoff : integer, float, or None (default: None)
(8)             If specified, the maximum flow algorithm will terminate when the
(8)             flow value reaches or exceeds the cutoff. This only works for flows
(8)             that support the cutoff parameter (most do) and is ignored otherwise.
(4)         Returns
(4)         -------
(4)         K : integer
(8)             Edge connectivity for G, or local edge connectivity if source
(8)             and target were provided
(4)         Examples
(4)         --------
(4)         >>> # Platonic icosahedral graph is 5-edge-connected
(4)         >>> G = nx.icosahedral_graph()
(4)         >>> nx.edge_connectivity(G)
(4)         5
(4)         You can use alternative flow algorithms for the underlying
(4)         maximum flow computation. In dense networks the algorithm
(4)         :meth:`shortest_augmenting_path` will usually perform better
(4)         than the default :meth:`edmonds_karp`, which is faster for
(4)         sparse networks with highly skewed degree distributions.
(4)         Alternative flow functions have to be explicitly imported
(4)         from the flow package.
(4)         >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)         >>> nx.edge_connectivity(G, flow_func=shortest_augmenting_path)
(4)         5
(4)         If you specify a pair of nodes (source and target) as parameters,
(4)         this function returns the value of local edge connectivity.
(4)         >>> nx.edge_connectivity(G, 3, 7)
(4)         5
(4)         If you need to perform several local computations among different
(4)         pairs of nodes on the same graph, it is recommended that you reuse
(4)         the data structures used in the maximum flow computations. See
(4)         :meth:`local_edge_connectivity` for details.
(4)         Notes
(4)         -----
(4)         This is a flow based implementation of global edge connectivity.
(4)         For undirected graphs the algorithm works by finding a 'small'
(4)         dominating set of nodes of G (see algorithm 7 in [1]_ ) and
(4)         computing local maximum flow (see :meth:`local_edge_connectivity`)
(4)         between an arbitrary node in the dominating set and the rest of
(4)         nodes in it. This is an implementation of algorithm 6 in [1]_ .
```

```
    For directed graphs, the algorithm does n calls to the maximum
    flow function. This is an implementation of algorithm 8 in [1]_ .

65: (4)                 :meth:`shortest_augmenting_path`
66: (4)                 Examples
67: (4)                 --------
```

```
68: (4)                 This function is not imported in the base NetworkX namespace, so you
69: (4)                 have to explicitly import it from the connectivity package:
70: (4)                 >>> from networkx.algorithms.connectivity import minimum_st_edge_cut
71: (4)                 We use in this example the platonic icosahedral graph, which has edge
72: (4)                 connectivity 5.
73: (4)                 >>> G = nx.icosahedral_graph()
74: (4)                 >>> len(minimum_st_edge_cut(G, 0, 6))
75: (4)                 5
76: (4)                 If you need to compute local edge cuts on several pairs of
77: (4)                 nodes in the same graph, it is recommended that you reuse the
78: (4)                 data structures that NetworkX uses in the computation: the
79: (4)                 auxiliary digraph for edge connectivity, and the residual
80: (4)                 network for the underlying maximum flow computation.
81: (4)                 Example of how to compute local edge cuts among all pairs of
82: (4)                 nodes of the platonic icosahedral graph reusing the data
83: (4)                 structures.
84: (4)                 >>> import itertools
85: (4)                 >>> # You also have to explicitly import the function for
86: (4)                 >>> # building the auxiliary digraph from the connectivity package
87: (4)                 >>> from networkx.algorithms.connectivity import
build_auxiliary_edge_connectivity
88: (4)                 >>> H = build_auxiliary_edge_connectivity(G)
89: (4)                 >>> # And the function for building the residual network from the
90: (4)                 >>> # flow package
91: (4)                 >>> from networkx.algorithms.flow import build_residual_network
92: (4)                 >>> # Note that the auxiliary digraph has an edge attribute named capacity
93: (4)                 >>> R = build_residual_network(H, "capacity")
94: (4)                 >>> result = dict.fromkeys(G, dict())
95: (4)                 >>> # Reuse the auxiliary digraph and the residual network by passing them
96: (4)                 >>> # as parameters
97: (4)                 >>> for u, v in itertools.combinations(G, 2):
98: (4)                 ...     k = len(minimum_st_edge_cut(G, u, v, auxiliary=H, residual=R))
99: (4)                 ...     result[u][v] = k

132: (4)                from target in G.
133: (4)                This function returns the set of nodes of minimum cardinality that,
```

```
(4)                 if removed, would destroy all paths among source and target in G.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(4)                 s : node
(8)                     Source node.
(4)                 t : node
(8)                     Target node.
(4)                 flow_func : function
(8)                     A function for computing the maximum flow among a pair of nodes.
(8)                     The function has to accept at least three parameters: a Digraph,
(8)                     a source node, and a target node. And return a residual network
(8)                     that follows NetworkX conventions (see :meth:`maximum_flow` for
(8)                     details). If flow_func is None, the default maximum flow function
(8)                     (:meth:`edmonds_karp`) is used. See below for details. The choice
(8)                     of the default function may change from version to version and
(8)                     should not be relied on. Default value: None.
(4)                 auxiliary : NetworkX DiGraph
(8)                     Auxiliary digraph to compute flow based node connectivity. It has
(8)                     to have a graph attribute called mapping with a dictionary mapping
(8)                     node names in G and in the auxiliary digraph. If provided
(8)                     it will be reused instead of recreated. Default value: None.
(4)                 residual : NetworkX DiGraph
(8)                     Residual network to compute maximum flow. If provided it will be
(8)                     reused instead of recreated. Default value: None.
(4)                 Returns
(4)                 -------
(4)                 cutset : set
(8)                     Set of nodes that, if removed, would destroy all paths between
(8)                     source and target in G.
(4)                 Examples
(4)                 --------
(4)                 This function is not imported in the base NetworkX namespace, so you
(4)                 have to explicitly import it from the connectivity package:
(4)                 >>> from networkx.algorithms.connectivity import minimum_st_node_cut
(4)                 We use in this example the platonic icosahedral graph, which has node
(4)                 connectivity 5.
(4)                 >>> G = nx.icosahedral_graph()
(4)                 >>> len(minimum_st_node_cut(G, 0, 6))
(4)                 5
(4)                 If you need to compute local st cuts between several pairs of
(4)                 nodes in the same graph, it is recommended that you reuse the
(4)                 data structures that NetworkX uses in the computation: the
(4)                 auxiliary digraph for node connectivity and node cuts, and the
(4)                 residual network for the underlying maximum flow computation.
(4)                 Example of how to compute local st node cuts reusing the data
(4)                 structures:
(4)                 >>> # You also have to explicitly import the function for
(4)                 >>> # building the auxiliary digraph from the connectivity package
(4)                 >>> from networkx.algorithms.connectivity import
build_auxiliary_node_connectivity
(4)                 >>> H = build_auxiliary_node_connectivity(G)
(4)                 >>> # And the function for building the residual network from the
(4)                 >>> # flow package
(4)                 >>> from networkx.algorithms.flow import build_residual_network
(4)                 >>> # Note that the auxiliary digraph has an edge attribute named capacity
(4)                 >>> R = build_residual_network(H, "capacity")
(4)                 >>> # Reuse the auxiliary digraph and the residual network by passing them
(4)                 >>> # as parameters
(4)                 >>> len(minimum_st_node_cut(G, 0, 6, auxiliary=H, residual=R))
(4)                 5
(4)                 You can also use alternative flow algorithms for computing minimum st
(4)                 node cuts. For instance, in dense networks the algorithm
(4)                 :meth:`shortest_augmenting_path` will usually perform better than
(4)                 the default :meth:`edmonds_karp` which is faster for sparse
(4)                 networks with highly skewed degree distributions. Alternative flow
(4)                 functions have to be explicitly imported from the flow package.
(4)                 >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)                 >>> len(minimum_st_node_cut(G, 0, 6, flow_func=shortest_augmenting_path))
```

```
(4)                 5
(4)                 Notes
(4)                 -----
(4)                 This is a flow based implementation of minimum node cut. The algorithm
(4)                 is based in solving a number of maximum flow computations to determine
(4)                 the capacity of the minimum cut on an auxiliary directed network that
(4)                 corresponds to the minimum node cut of G. It handles both directed
(4)                 and undirected graphs. This implementation is based on algorithm 11
(4)                 in [1]_.

(4)                 set of nodes of minimum cardinality that, if removed, would destroy
(4)                 all paths among source and target in G. If not, it returns a set
(4)                 of nodes of minimum cardinality that disconnects G.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(4)                 s : node
(8)                     Source node. Optional. Default value: None.
(4)                 t : node
(8)                     Target node. Optional. Default value: None.
(4)                 flow_func : function
(8)                     A function for computing the maximum flow among a pair of nodes.
(8)                     The function has to accept at least three parameters: a Digraph,
(8)                     a source node, and a target node. And return a residual network
(8)                     that follows NetworkX conventions (see :meth:`maximum_flow` for
(8)                     details). If flow_func is None, the default maximum flow function
(8)                     (:meth:`edmonds_karp`) is used. See below for details. The
(8)                     choice of the default function may change from version
(8)                     to version and should not be relied on. Default value: None.
(4)                 Returns
(4)                 -------
(4)                 cutset : set
(8)                     Set of nodes that, if removed, would disconnect G. If source
(8)                     and target nodes are provided, the set contains the nodes that
(8)                     if removed, would destroy all paths between source and target.
(4)                 Examples
```

```
    --------
    >>> # Platonic icosahedral graph has node connectivity 5
    >>> G = nx.icosahedral_graph()
    >>> node_cut = nx.minimum_node_cut(G)
    >>> len(node_cut)
    5
    You can use alternative flow algorithms for the underlying maximum
    flow computation. In dense networks the algorithm
    :meth:`shortest_augmenting_path` will usually perform better
    than the default :meth:`edmonds_karp`, which is faster for
    sparse networks with highly skewed degree distributions. Alternative
    flow functions have to be explicitly imported from the flow package.
    >>> from networkx.algorithms.flow import shortest_augmenting_path
    >>> node_cut == nx.minimum_node_cut(G, flow_func=shortest_augmenting_path)
    True
    If you specify a pair of nodes (source and target) as parameters,
    this function returns a local st node cut.
    >>> len(nx.minimum_node_cut(G, 3, 7))
    5
    If you need to perform several local st cuts among different
    pairs of nodes on the same graph, it is recommended that you reuse
    the data structures used in the maximum flow computations. See
    :meth:`minimum_st_node_cut` for details.
    Notes
    -----
    This is a flow based implementation of minimum node cut. The algorithm
    is based in solving a number of maximum flow computations to determine
    the capacity of the minimum cut on an auxiliary directed network that
    corresponds to the minimum node cut of G. It handles both directed
    and undirected graphs. This implementation is based on algorithm 11
    in [1]_.

(4)                 Notes
```

```
    -----
    This is a flow based implementation of minimum edge cut. For
    undirected graphs the algorithm works by finding a 'small' dominating
    set of nodes of G (see algorithm 7 in [1]_) and computing the maximum
    flow between an arbitrary node in the dominating set and the rest of
    nodes in it. This is an implementation of algorithm 6 in [1]_. For
    directed graphs, the algorithm does n calls to the max flow function.
    The function raises an error if the directed graph is not weakly
    connected and returns an empty set if it is weakly connected.
    It is an implementation of algorithm 8 in [1]_.

(4)                 r"""Computes node disjoint paths between source and target.
(4)                 Node disjoint paths are paths that only share their first and last
(4)                 nodes. The number of node independent paths between two nodes is
(4)                 equal to their local node connectivity.
(4)                 Parameters
```

```
    ----------
    G : NetworkX graph
    s : node
        Source node.
    t : node
        Target node.
    flow_func : function
        A function for computing the maximum flow among a pair of nodes.
        The function has to accept at least three parameters: a Digraph,
        a source node, and a target node. And return a residual network
        that follows NetworkX conventions (see :meth:`maximum_flow` for
        details). If flow_func is None, the default maximum flow function
        (:meth:`edmonds_karp`) is used. See below for details. The choice
        of the default function may change from version to version and
        should not be relied on. Default value: None.
    cutoff : integer or None (default: None)
        Maximum number of paths to yield. If specified, the maximum flow
        algorithm will terminate when the flow value reaches or exceeds the
        cutoff. This only works for flows that support the cutoff parameter
        (most do) and is ignored otherwise.
    auxiliary : NetworkX DiGraph
        Auxiliary digraph to compute flow based node connectivity. It has
        to have a graph attribute called mapping with a dictionary mapping
        node names in G and in the auxiliary digraph. If provided
        it will be reused instead of recreated. Default value: None.
    residual : NetworkX DiGraph
        Residual network to compute maximum flow. If provided it will be
        reused instead of recreated. Default value: None.
    Returns
    -------
    paths : generator
        Generator of node disjoint paths.
    Raises
    ------
    NetworkXNoPath
        If there is no path between source and target.
    NetworkXError
        If source or target are not in the graph G.
    Examples
    --------
    We use in this example the platonic icosahedral graph, which has node
    connectivity 5, thus there are 5 node disjoint paths between any pair
    of non neighbor nodes.
    >>> G = nx.icosahedral_graph()
    >>> len(list(nx.node_disjoint_paths(G, 0, 6)))
    5
    If you need to compute node disjoint paths between several pairs of
    nodes in the same graph, it is recommended that you reuse the
    data structures that NetworkX uses in the computation: the
    auxiliary digraph for node connectivity and node cuts, and the
    residual network for the underlying maximum flow computation.
    Example of how to compute node disjoint paths reusing the data
    structures:
    >>> # You also have to explicitly import the function for
    >>> # building the auxiliary digraph from the connectivity package
    >>> from networkx.algorithms.connectivity import
build_auxiliary_node_connectivity
    >>> H = build_auxiliary_node_connectivity(G)
    >>> # And the function for building the residual network from the
    >>> # flow package
    >>> from networkx.algorithms.flow import build_residual_network
    >>> # Note that the auxiliary digraph has an edge attribute named capacity
    >>> R = build_residual_network(H, "capacity")
    >>> # Reuse the auxiliary digraph and the residual network by passing them
    >>> # as arguments
    >>> len(list(nx.node_disjoint_paths(G, 0, 6, auxiliary=H, residual=R)))
    5
    You can also use alternative flow algorithms for computing node disjoint
    paths. For instance, in dense networks the algorithm
```

```

109: (4)                """Finds set of edges to k-edge-connect G.
110: (4)                Adding edges from the augmentation to G make it impossible to disconnect G
111: (4)                unless k or more edges are removed. This function uses the most efficient
112: (4)                function available (depending on the value of k and if the problem is
113: (4)                weighted or unweighted) to search for a minimum weight subset of available
114: (4)                edges that k-edge-connects G. In general, finding a k-edge-augmentation is
115: (4)                NP-hard, so solutions are not guaranteed to be minimal. Furthermore, a
116: (4)                k-edge-augmentation may not exist.
117: (4)                Parameters
118: (4)                ----------
119: (4)                G : NetworkX graph
120: (7)                   An undirected graph.
121: (4)                k : integer
122: (8)                    Desired edge connectivity
123: (4)                avail : dict or a set of 2 or 3 tuples
124: (8)                    The available edges that can be used in the augmentation.
125: (8)                    If unspecified, then all edges in the complement of G are available.
126: (8)                    Otherwise, each item is an available edge (with an optional weight).
127: (8)                    In the unweighted case, each item is an edge ``(u, v)``.
128: (8)                    In the weighted case, each item is a 3-tuple ``(u, v, d)`` or a dict
129: (8)                    with items ``(u, v): d``.  The third item, ``d``, can be a dictionary
130: (8)                    or a real number.  If ``d`` is a dictionary ``d[weight]``
131: (8)                    correspondings to the weight.
132: (4)                weight : string
133: (8)                    key to use to find weights if ``avail`` is a set of 3-tuples where the
134: (8)                    third item in each tuple is a dictionary.
135: (4)                partial : boolean
136: (8)                    If partial is True and no feasible k-edge-augmentation exists, then
all
```

```
    a partial k-edge-augmentation is generated. Adding the edges in a
    partial augmentation to G, minimizes the number of k-edge-connected
    components and maximizes the edge connectivity between those
    components. For details, see :func:`partial_k_edge_augmentation`.
Yields
------
edge : tuple
    Edges that, once added to G, would cause G to become k-edge-connected.
    If partial is False, an error is raised if this is not possible.
    Otherwise, generated edges form a partial augmentation, which
    k-edge-connects any part of G where it is possible, and maximally
    connects the remaining parts.
Raises
------
NetworkXUnfeasible
    If partial is False and no k-edge-augmentation exists.
NetworkXNotImplemented
    If the input graph is directed or a multigraph.
ValueError:
    If k is less than 1
Notes
-----
When k=1 this returns an optimal solution.
When k=2 and ``avail`` is None, this returns an optimal solution.
Otherwise when k=2, this returns a 2-approximation of the optimal solution.

For k>3, this problem is NP-hard and this uses a randomized algorithm that
    produces a feasible solution, but provides no guarantees on the
    solution weight.
Examples

    """Finds minimum weight set of edges to connect G.
    Equivalent to :func:`k_edge_augmentation` when k=1. Adding the resulting
    edges to G will make it 1-edge-connected. The solution is optimal for both
    weighted and non-weighted variants.
    Parameters
    ----------
    G : NetworkX graph
       An undirected graph.
    avail : dict or a set of 2 or 3 tuples
        For more details, see :func:`k_edge_augmentation`.
    weight : string
        key to use to find weights if ``avail`` is a set of 3-tuples.
        For more details, see :func:`k_edge_augmentation`.
    partial : boolean
        If partial is True and no feasible k-edge-augmentation exists, then the
        augmenting edges minimize the number of connected components.
    Yields
    ------
    edge : tuple
        Edges in the one-augmentation of G
    Raises
    ------
    NetworkXUnfeasible
        If partial is False and no one-edge-augmentation exists.
    Notes
    -----
    Uses either :func:`unconstrained_one_edge_augmentation` or
    :func:`weighted_one_edge_augmentation` depending on whether ``avail`` is
```

```
(4)                 specified. Both algorithms are based on finding a minimum spanning tree.
(4)                 As such both algorithms find optimal solutions and run in linear time.

(4)                 Input: a graph G.
(4)                 First find the bridge components of G and collapse each bridge-cc into a
(4)                 node of a metagraph graph C, which is guaranteed to be a forest of trees.
(4)                 C contains p "leafs" --- nodes with exactly one incident edge.
(4)                 C contains q "isolated nodes" --- nodes with no incident edges.
(4)                 Theorem: If p + q > 1, then at least :math:`ceil(p / 2) + q` edges are
(8)                     needed to bridge connect C. This algorithm achieves this min number.
(4)                 The method first adds enough edges to make G into a tree and then pairs
(4)                 leafs in a simple fashion.
(4)                 Let n be the number of trees in C. Let v(i) be an isolated vertex in the
(4)                 i-th tree if one exists, otherwise it is a pair of distinct leafs nodes
(4)                 in the i-th tree. Alternating edges from these sets (i.e.  adding edges
(4)                 A1 = [(v(i)[0], v(i + 1)[1]), v(i + 1)[0], v(i + 2)[1])...]) connects C
(4)                 into a tree T. This tree has p' = p + 2q - 2(n -1) leafs and no isolated
(4)                 vertices. A1 has n - 1 edges. The next step finds ceil(p' / 2) edges to
(4)                 biconnect any tree with p' leafs.
(4)                 Convert T into an arborescence T' by picking an arbitrary root node with
(4)                 degree >= 2 and directing all edges away from the root. Note the
(4)                 implementation implicitly constructs T'.
(4)                 The leafs of T are the nodes with no existing edges in T'.
(4)                 Order the leafs of T' by DFS preorder. Then break this list in half
(4)                 and add the zipped pairs to A2.
(4)                 The set A = A1 + A2 is the minimum augmentation in the metagraph.
(4)                 To convert this to edges in the original graph

(0)             def weighted_bridge_augmentation(G, avail, weight=None):
(4)                 """Finds an approximate min-weight 2-edge-augmentation of G.
(4)                 This is an implementation of the approximation algorithm detailed in [1]_.
(4)                 It chooses a set of edges from avail to add to G that renders it
(4)                 2-edge-connected if such a subset exists.  This is done by finding a
(4)                 minimum spanning arborescence of a specially constructed metagraph.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(7)                    An undirected graph.
(4)                 avail : set of 2 or 3 tuples.
(8)                     candidate edges (with optional weights) to choose from
(4)                 weight : string
(8)                     key to use to find weights if avail is a set of 3-tuples where the
(8)                     third item in each tuple is a dictionary.
(4)                 Yields
(4)                 ------
(4)                 edge : tuple
(8)                     Edges in the subset of avail chosen to bridge augment G.
(4)                 Notes
(4)                 -----
(4)                 Finding a weighted 2-edge-augmentation is NP-hard.
(4)                 Any edge not in ``avail`` is considered to have a weight of infinity.
(4)                 The approximation factor is 2 if ``G`` is connected and 3 if it is not.
(4)                 Runs in :math:`O(m + n log(n))` time

(4)                 G : NetworkX graph
```

```
(7)                 An undirected graph.
(4)             k : integer
(8)                 Desired edge connectivity
(4)             avail : dict or a set of 2 or 3 tuples
(8)                 For more details, see :func:`k_edge_augmentation`.
(4)             weight : string
(8)                 key to use to find weights if ``avail`` is a set of 3-tuples.
(8)                 For more details, see :func:`k_edge_augmentation`.
(4)             seed : integer, random_state, or None (default)
(8)                 Indicator of random number generation state.
(8)                 See :ref:`Randomness<randomness>`.
(4)             Yields
(4)             ------
(4)             edge : tuple
(8)                 Edges in the greedy augmentation of G
(4)             Notes
(4)             -----
(4)             The algorithm is simple. Edges are incrementally added between parts of
the
(4)             graph that are not yet locally k-edge-connected. Then edges are from the
(4)             augmenting set are pruned as long as local-edge-connectivity is not
broken.
(4)             This algorithm is greedy and does not provide optimality guarantees. It
(4)             exists only to provide :func:`k_edge_augmentation` with the ability to
(4)             generate a feasible solution for arbitrary k.

        Notes
        -----
        Given G=(V, E), initialize an empty auxiliary graph A.
        Choose an arbitrary source node s.  Initialize a set N of available
        nodes (that can be used as the sink). The algorithm picks an
        arbitrary node t from N - {s}, and then computes the minimum st-cut
        (S, T) with value w. If G is directed the minimum of the st-cut or
        the ts-cut is used instead. Then, the edge (s, t) is added to the
        auxiliary graph with weight w. The algorithm is called recursively
        first using S as the available nodes and s as the source, and then
        using T and t. Recursion stops when the source is the only available
        node.
        Parameters

(4)             """General algorithm to find all maximal k-edge-connected subgraphs in
`G`.
(4)             Parameters
(4)             ----------
(4)             G : nx.Graph
(7)                Graph in which all maximal k-edge-connected subgraphs will be found.
(4)             k : int
(4)             Yields
(4)             ------
(4)             k_edge_subgraphs : Graph instances that are k-edge-subgraphs
(8)                 Each k-edge-subgraph contains a maximal set of nodes that defines a
(8)                 subgraph of `G` that is k-edge-connected.
(4)             Notes
(4)             -----
(4)             Implementation of the basic algorithm from [1]_.  The basic idea is to
find
(4)             a global minimum cut of the graph. If the cut value is at least k, then
the
(4)             graph is a k-edge-connected subgraph and can be added to the results.
(4)             Otherwise, the cut is used to split the graph in two and the procedure is
(4)             applied recursively. If the graph is just a single node, then it is also
(4)             added to the results. At the end, each result is either guaranteed to be
(4)             a single node or a subgraph of G that is k-edge-connected.
(4)             This implementation contains optimizations for reducing the number of
calls
(4)             to max-flow, but there are other optimizations in [1]_ that could be
(4)             implemented.

@nx._dispatchable
def all_node_cuts(G, k=None, flow_func=None):
    r"""Returns all minimum k cutsets of an undirected graph G.
    This implementation is based on Kanevsky's algorithm [1]_ for finding all
    minimum-size node cut-sets of an undirected graph G; ie the set (or sets)
    of nodes of cardinality equal to the node connectivity of G. Thus if
    removed, would break G into two or more connected components.
    Parameters
    ----------
    G : NetworkX graph
        Undirected graph
    k : Integer
        Node connectivity of the input graph. If k is None, then it is
        computed. Default value: None.
    flow_func : function
        Function to perform the underlying flow computations. Default value is
        :func:`~networkx.algorithms.flow.edmonds_karp`. This function performs
        better in sparse graphs with right tailed degree distributions.
        :func:`~networkx.algorithms.flow.shortest_augmenting_path` will
        perform better in denser graphs.
    Returns
    -------
    cuts : a generator of node cutsets
        Each node cutset has cardinality equal to the node connectivity of
        the input graph.
    Examples
    --------
    >>> # A two-dimensional grid graph has 4 cutsets of cardinality 2
    >>> G = nx.grid_2d_graph(5, 5)
    >>> cutsets = list(nx.all_node_cuts(G))
    >>> len(cutsets)
    4
    >>> all(2 == len(cutset) for cutset in cutsets)
    True
    >>> nx.node_connectivity(G)
    2
    Notes
    -----
    This implementation is based on the sequential algorithm for finding all
    minimum-size separating vertex sets in a graph [1]_. The main idea is to
    compute minimum cuts using local maximum flow computations among a set
    of nodes of highest degree and all other non-adjacent nodes in the Graph.
    Once we find a minimum cut, we add an edge between the high degree
    node and the target node of the local maximum flow computation to make
    sure that we will not find that minimum cut again.

122: (4)                    r"""Find a minimum cost flow satisfying all demands in digraph G.
123: (4)                    This is a capacity scaling successive shortest augmenting path algorithm.
124: (4)                    G is a digraph with edge costs and capacities and in which nodes
125: (4)                    have demand, i.e., they want to send or receive some amount of
126: (4)                    flow. A negative demand means that the node wants to send flow, a
127: (4)                    positive demand means that the node want to receive flow. A flow on
128: (4)                    the digraph G satisfies all demand if the net flow into each node
129: (4)                    is equal to the demand of that node.
130: (4)                    Parameters
131: (4)                    ----------
132: (4)                    G : NetworkX graph
133: (8)                        DiGraph or MultiDiGraph on which a minimum cost flow satisfying all
134: (8)                        demands is to be found.
135: (4)                    demand : string
136: (8)                        Nodes of the graph G are expected to have an attribute demand
137: (8)                        that indicates how much flow a node wants to send (negative
138: (8)                        demand) or receive (positive demand). Note that the sum of the
139: (8)                        demands should be 0 otherwise the problem in not feasible. If
140: (8)                        this attribute is not present, a node is considered to have 0
141: (8)                        demand. Default value: 'demand'.
142: (4)                    capacity : string
143: (8)                        Edges of the graph G are expected to have an attribute capacity
144: (8)                        that indicates how much flow the edge can support. If this
145: (8)                        attribute is not present, the edge is considered to have
146: (8)                        infinite capacity. Default value: 'capacity'.
147: (4)                    weight : string
148: (8)                        Edges of the graph G are expected to have an attribute weight
149: (8)                        that indicates the cost incurred by sending one unit of flow on
150: (8)                        that edge. If not present, the weight is considered to be 0.
151: (8)                        Default value: 'weight'.
152: (4)                    heap : class
153: (8)                        Type of heap to be used in the algorithm. It should be a subclass of
154: (8)                        :class:`MinHeap` or implement a compatible interface.
155: (8)                        If a stock heap implementation is to be used, :class:`BinaryHeap` is
156: (8)                        recommended over :class:`PairingHeap` for Python implementations
without
157: (8)                        optimized attribute accesses (e.g., CPython) despite a slower
158: (8)                        asymptotic running time. For Python implementations with optimized
159: (8)                        attribute accesses (e.g., PyPy), :class:`PairingHeap` provides better
160: (8)                        performance. Default value: :class:`BinaryHeap`.
161: (4)                    Returns
162: (4)                    -------
163: (4)                    flowCost : integer
164: (8)                        Cost of a minimum cost flow satisfying all demands.
165: (4)                    flowDict : dictionary
166: (8)                        If G is a digraph, a dict-of-dicts keyed by nodes such that
167: (8)                        flowDict[u][v] is the flow on edge (u, v).
168: (8)                        If G is a MultiDiGraph, a dict-of-dicts-of-dicts keyed by nodes
169: (8)                        so that flowDict[u][v][key] is the flow on edge (u, v, key).
170: (4)                    Raises
171: (4)                    ------
172: (4)                    NetworkXError
173: (8)                        This exception is raised if the input graph is not directed,
```

```
(8)                 not connected.
(4)             NetworkXUnfeasible
(8)                 This exception is raised in the following situations:
(12)                    * The sum of the demands is not zero. Then, there is no
(14)                      flow satisfying all demands.
(12)                    * There is no flow satisfying all demand.
(4)             NetworkXUnbounded
(8)                 This exception is raised if the digraph G has a cycle of
(8)                 negative cost and infinite capacity. Then, the cost of a flow
(8)                 satisfying all demands is unbounded below.
(4)             Notes
(4)             -----
(4)             This algorithm does not work if edge weights are floating-point numbers.

13: (4)                 r"""Find a maximum single-commodity flow using Boykov-Kolmogorov
algorithm.
14: (4)                 This function returns the residual network resulting after computing
15: (4)                 the maximum flow. See below for details about the conventions
16: (4)                 NetworkX uses for defining residual networks.
17: (4)                 This algorithm has worse case complexity $O(n^2 m |C|)$ for $n$ nodes, $m$
18: (4)                 edges, and $|C|$ the cost of the minimum cut [1]_. This implementation
19: (4)                 uses the marking heuristic defined in [2]_ which improves its running
20: (4)                 time in many practical problems.
21: (4)                 Parameters
22: (4)                 ----------
23: (4)                 G : NetworkX graph
24: (8)                     Edges of the graph are expected to have an attribute called
25: (8)                     'capacity'. If this attribute is not present, the edge is

35: (8)                     infinite capacity. Default value: 'capacity'.
36: (4)                 residual : NetworkX graph
37: (8)                     Residual network on which the algorithm is to be executed. If None, a
38: (8)                     new residual network is created. Default value: None.
39: (4)                 value_only : bool
40: (8)                     If True compute only the value of the maximum flow. This parameter
41: (8)                     will be ignored by this algorithm because it is not applicable.
42: (4)                 cutoff : integer, float
43: (8)                     If specified, the algorithm will terminate when the flow value reaches
44: (8)                     or exceeds the cutoff. In this case, it may be unable to immediately
45: (8)                     determine a minimum cut. Default value: None.
46: (4)                 Returns
```

```
(4)                 -------
(4)                 R : NetworkX DiGraph
(8)                     Residual network after computing the maximum flow.
(4)                 Raises
(4)                 ------
(4)                 NetworkXError
(8)                     The algorithm does not support MultiGraph and MultiDiGraph. If
(8)                     the input graph is an instance of one of these two classes, a
(8)                     NetworkXError is raised.
(4)                 NetworkXUnbounded
(8)                     If the graph has a path of infinite capacity, the value of a
(8)                     feasible flow on the graph is unbounded above and the function
(8)                     raises a NetworkXUnbounded.
(4)                 See also

(4)                 :meth:`shortest_augmenting_path`
(4)                 Notes
(4)                 -----
(4)                 The residual network :samp:`R` from an input graph :samp:`G` has the
(4)                 same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
(4)                 of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
(4)                 self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
(4)                 in :samp:`G`.
(4)                 For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
(4)                 is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
(4)                 in :samp:`G` or zero otherwise. If the capacity is infinite,
(4)                 :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
(4)                 that does not affect the solution of the problem. This value is stored in
(4)                 :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
(4)                 :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
(4)                 satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
(4)                 The flow value, defined as the total flow into :samp:`t`, the sink, is
(4)                 stored in :samp:`R.graph['flow_value']`. If :samp:`cutoff` is not
(4)                 specified, reachability to :samp:`t` using only edges :samp:`(u, v)` such
(4)                 that :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
(4)                 :samp:`s`-:samp:`t` cut.
(4)                 Examples
(4)                 --------
(4)                 >>> from networkx.algorithms.flow import boykov_kolmogorov
(4)                 The functions that implement flow algorithms and output a residual
(4)                 network, such as this one, are not imported to the base NetworkX
(4)                 namespace, so you have to explicitly import them from the flow package.
(4)                 >>> G = nx.DiGraph()
(4)                 >>> G.add_edge("x", "a", capacity=3.0)
(4)                 >>> G.add_edge("x", "b", capacity=1.0)
(4)                 >>> G.add_edge("a", "c", capacity=3.0)
(4)                 >>> G.add_edge("b", "c", capacity=5.0)
(4)                 >>> G.add_edge("b", "d", capacity=4.0)
(4)                 >>> G.add_edge("d", "e", capacity=2.0)
(4)                 >>> G.add_edge("c", "y", capacity=2.0)
(4)                 >>> G.add_edge("e", "y", capacity=3.0)
(4)                 >>> R = boykov_kolmogorov(G, "x", "y")
(4)                 >>> flow_value = nx.maximum_flow_value(G, "x", "y")
(4)                 >>> flow_value
(4)                 3.0
(4)                 >>> flow_value == R.graph["flow_value"]
(4)                 True
(4)                 A nice feature of the Boykov-Kolmogorov algorithm is that a partition
(4)                 of the nodes that defines a minimum cut can be easily computed based
(4)                 on the search trees used during the algorithm. These trees are stored
(4)                 in the graph attribute `trees` of the residual network.
(4)                 >>> source_tree, target_tree = R.graph["trees"]
(4)                 >>> partition = (set(source_tree), set(G) - set(source_tree))
(4)                 Or equivalently:
(4)                 >>> partition = (set(G) - set(target_tree), set(target_tree))

@nx._dispatchable(edge_attrs={"capacity": float("inf")}, returns_graph=True)
def dinitz(G, s, t, capacity="capacity", residual=None, value_only=False, cutoff=None):
    """Find a maximum single-commodity flow using Dinitz' algorithm.
    This function returns the residual network resulting after computing
    the maximum flow. See below for details about the conventions
    NetworkX uses for defining residual networks.
    This algorithm has a running time of $O(n^2 m)$ for $n$ nodes and $m$
    edges [1]_.
    Parameters
    ----------
    G : NetworkX graph
        Edges of the graph are expected to have an attribute called
        'capacity'. If this attribute is not present, the edge is
        considered to have infinite capacity.
    s : node
        Source node for the flow.
    t : node
        Sink node for the flow.
    capacity : string
        Edges of the graph G are expected to have an attribute capacity
        that indicates how much flow the edge can support. If this
        attribute is not present, the edge is considered to have
        infinite capacity. Default value: 'capacity'.
    residual : NetworkX graph
        Residual network on which the algorithm is to be executed. If None, a
        new residual network is created. Default value: None.
    value_only : bool
        If True compute only the value of the maximum flow. This parameter
        will be ignored by this algorithm because it is not applicable.
    cutoff : integer, float
        If specified, the algorithm will terminate when the flow value reaches
        or exceeds the cutoff. In this case, it may be unable to immediately
        determine a minimum cut. Default value: None.
    Returns
    -------
    R : NetworkX DiGraph
        Residual network after computing the maximum flow.
    Raises
    ------
    NetworkXError
        The algorithm does not support MultiGraph and MultiDiGraph. If
        the input graph is an instance of one of these two classes, a
        NetworkXError is raised.
    NetworkXUnbounded
        If the graph has a path of infinite capacity, the value of a
        feasible flow on the graph is unbounded above and the function
        raises a NetworkXUnbounded.

    :meth:`minimum_cut`
    :meth:`preflow_push`
    :meth:`shortest_augmenting_path`
    Notes
    -----
    The residual network :samp:`R` from an input graph :samp:`G` has the
    same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
    of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
    self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
    in :samp:`G`.
    For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
    is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
    in :samp:`G` or zero otherwise. If the capacity is infinite,
    :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
    that does not affect the solution of the problem. This value is stored in
    :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
```

```
(4)                 :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
(4)                 satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
(4)                 The flow value, defined as the total flow into :samp:`t`, the sink, is
(4)                 stored in :samp:`R.graph['flow_value']`. If :samp:`cutoff` is not
(4)                 specified, reachability to :samp:`t` using only edges :samp:`(u, v)` such
(4)                 that :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
(4)                 :samp:`s`-:samp:`t` cut.
(4)                 Examples
(4)                 --------
(4)                 >>> from networkx.algorithms.flow import dinitz
(4)                 The functions that implement flow algorithms and output a residual
(4)                 network, such as this one, are not imported to the base NetworkX
(4)                 namespace, so you have to explicitly import them from the flow package.
(4)                 >>> G = nx.DiGraph()
(4)                 >>> G.add_edge("x", "a", capacity=3.0)
(4)                 >>> G.add_edge("x", "b", capacity=1.0)
(4)                 >>> G.add_edge("a", "c", capacity=3.0)
(4)                 >>> G.add_edge("b", "c", capacity=5.0)
(4)                 >>> G.add_edge("b", "d", capacity=4.0)
(4)                 >>> G.add_edge("d", "e", capacity=2.0)
(4)                 >>> G.add_edge("c", "y", capacity=2.0)
(4)                 >>> G.add_edge("e", "y", capacity=3.0)
(4)                 >>> R = dinitz(G, "x", "y")
(4)                 >>> flow_value = nx.maximum_flow_value(G, "x", "y")
(4)                 >>> flow_value
(4)                 3.0
(4)                 >>> flow_value == R.graph["flow_value"]
(4)                 True

103: (4)                the maximum flow. See below for details about the conventions
104: (4)                NetworkX uses for defining residual networks.
105: (4)                This algorithm has a running time of $O(n m^2)$ for $n$ nodes and $m$
106: (4)                edges.
107: (4)                Parameters
108: (4)                ----------
109: (4)                G : NetworkX graph
110: (8)                    Edges of the graph are expected to have an attribute called
111: (8)                    'capacity'. If this attribute is not present, the edge is
112: (8)                    considered to have infinite capacity.
113: (4)                s : node
114: (8)                    Source node for the flow.
115: (4)                t : node
116: (8)                    Sink node for the flow.
117: (4)                capacity : string
118: (8)                    Edges of the graph G are expected to have an attribute capacity
119: (8)                    that indicates how much flow the edge can support. If this
120: (8)                    attribute is not present, the edge is considered to have
121: (8)                    infinite capacity. Default value: 'capacity'.
122: (4)                residual : NetworkX graph
123: (8)                    Residual network on which the algorithm is to be executed. If None, a
124: (8)                    new residual network is created. Default value: None.
125: (4)                value_only : bool
126: (8)                    If True compute only the value of the maximum flow. This parameter
127: (8)                    will be ignored by this algorithm because it is not applicable.
128: (4)                cutoff : integer, float
129: (8)                    If specified, the algorithm will terminate when the flow value reaches
130: (8)                    or exceeds the cutoff. In this case, it may be unable to immediately
131: (8)                    determine a minimum cut. Default value: None.
132: (4)                Returns
133: (4)                -------
134: (4)                R : NetworkX DiGraph
135: (8)                    Residual network after computing the maximum flow.
136: (4)                Raises
137: (4)                ------
138: (4)                NetworkXError
139: (8)                    The algorithm does not support MultiGraph and MultiDiGraph. If
140: (8)                    the input graph is an instance of one of these two classes, a
141: (8)                    NetworkXError is raised.
142: (4)                NetworkXUnbounded
143: (8)                    If the graph has a path of infinite capacity, the value of a
144: (8)                    feasible flow on the graph is unbounded above and the function
145: (8)                    raises a NetworkXUnbounded.
146: (4)                See also

```
152: (4)                Notes
153: (4)                -----
154: (4)                The residual network :samp:`R` from an input graph :samp:`G` has the
155: (4)                same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
156: (4)                of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
157: (4)                self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
158: (4)                in :samp:`G`.
159: (4)                For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
160: (4)                is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
161: (4)                in :samp:`G` or zero otherwise. If the capacity is infinite,
162: (4)                :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
163: (4)                that does not affect the solution of the problem. This value is stored in
164: (4)                :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
165: (4)                :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
166: (4)                satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
167: (4)                The flow value, defined as the total flow into :samp:`t`, the sink, is
168: (4)                stored in :samp:`R.graph['flow_value']`. If :samp:`cutoff` is not
169: (4)                specified, reachability to :samp:`t` using only edges :samp:`(u, v)` such
170: (4)                that :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
171: (4)                :samp:`s`-:samp:`t` cut.
172: (4)                Examples
173: (4)                --------
174: (4)                >>> from networkx.algorithms.flow import edmonds_karp
175: (4)                The functions that implement flow algorithms and output a residual
176: (4)                network, such as this one, are not imported to the base NetworkX
177: (4)                namespace, so you have to explicitly import them from the flow package.
178: (4)                >>> G = nx.DiGraph()
179: (4)                >>> G.add_edge("x", "a", capacity=3.0)
180: (4)                >>> G.add_edge("x", "b", capacity=1.0)
181: (4)                >>> G.add_edge("a", "c", capacity=3.0)
182: (4)                >>> G.add_edge("b", "c", capacity=5.0)
183: (4)                >>> G.add_edge("b", "d", capacity=4.0)
184: (4)                >>> G.add_edge("d", "e", capacity=2.0)
185: (4)                >>> G.add_edge("c", "y", capacity=2.0)
186: (4)                >>> G.add_edge("e", "y", capacity=3.0)
187: (4)                >>> R = edmonds_karp(G, "x", "y")
188: (4)                >>> flow_value = nx.maximum_flow_value(G, "x", "y")
189: (4)                >>> flow_value
190: (4)                3.0
191: (4)                >>> flow_value == R.graph["flow_value"]
192: (4)                True
193: (4)                """

16: (4)                 Parameters
```

```
(4)                 ----------
(4)                 flowG : NetworkX graph
(8)                     Edges of the graph are expected to have an attribute called
(8)                     'capacity'. If this attribute is not present, the edge is
(8)                     considered to have infinite capacity.
(4)                 _s : node
(8)                     Source node for the flow.
(4)                 _t : node
(8)                     Sink node for the flow.
(4)                 capacity : string
(8)                     Edges of the graph G are expected to have an attribute capacity
(8)                     that indicates how much flow the edge can support. If this
(8)                     attribute is not present, the edge is considered to have
(8)                     infinite capacity. Default value: 'capacity'.
(4)                 flow_func : function
(8)                     A function for computing the maximum flow among a pair of nodes
(8)                     in a capacitated graph. The function has to accept at least three
(8)                     parameters: a Graph or Digraph, a source node, and a target node.
(8)                     And return a residual network that follows NetworkX conventions
(8)                     (see Notes). If flow_func is None, the default maximum
(8)                     flow function (:meth:`preflow_push`) is used. See below for
(8)                     alternative algorithms. The choice of the default function may change
(8)                     from version to version and should not be relied on. Default value:
(8)                     None.
(4)                 kwargs : Any other keyword parameter is passed to the function that
(8)                     computes the maximum flow.
(4)                 Returns
(4)                 -------
(4)                 flow_value : integer, float
(8)                     Value of the maximum flow, i.e., net outflow from the source.
(4)                 flow_dict : dict
(8)                     A dictionary containing the value of the flow that went through
(8)                     each edge.
(4)                 Raises
(4)                 ------
(4)                 NetworkXError
(8)                     The algorithm does not support MultiGraph and MultiDiGraph. If
(8)                     the input graph is an instance of one of these two classes, a
(8)                     NetworkXError is raised.
(4)                 NetworkXUnbounded
(8)                     If the graph has a path of infinite capacity, the value of a
(8)                     feasible flow on the graph is unbounded above and the function
(8)                     raises a NetworkXUnbounded.

(4)                 Notes
(4)                 -----
(4)                 The function used in the flow_func parameter has to return a residual
(4)                 network that follows NetworkX conventions:
(4)                 The residual network :samp:`R` from an input graph :samp:`G` has the
(4)                 same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
(4)                 of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
(4)                 self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
(4)                 in :samp:`G`.
(4)                 For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
(4)                 is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
(4)                 in :samp:`G` or zero otherwise. If the capacity is infinite,
(4)                 :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
(4)                 that does not affect the solution of the problem. This value is stored in
(4)                 :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
(4)                 :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
(4)                 satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
(4)                 The flow value, defined as the total flow into :samp:`t`, the sink, is
```

```
 86: (4)                 stored in :samp:`R.graph['flow_value']`. Reachability to :samp:`t` using
 87: (4)                 only edges :samp:`(u, v)` such that
 88: (4)                 :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
 89: (4)                 :samp:`s`-:samp:`t` cut.
 90: (4)                 Specific algorithms may store extra data in :samp:`R`.
 91: (4)                 The function should supports an optional boolean parameter value_only.
 When
 92: (4)                 True, it can optionally terminate the algorithm as soon as the maximum
 flow

 146: (8)                    attribute is not present, the edge is considered to have
 147: (8)                    infinite capacity. Default value: 'capacity'.
 148: (4)                flow_func : function
 149: (8)                    A function for computing the maximum flow among a pair of nodes
```

```
(8)                 in a capacitated graph. The function has to accept at least three
(8)                 parameters: a Graph or Digraph, a source node, and a target node.
(8)                 And return a residual network that follows NetworkX conventions
(8)                 (see Notes). If flow_func is None, the default maximum
(8)                 flow function (:meth:`preflow_push`) is used. See below for
(8)                 alternative algorithms. The choice of the default function may change
(8)                 from version to version and should not be relied on. Default value:
(8)                 None.
(4)             kwargs : Any other keyword parameter is passed to the function that
(8)                 computes the maximum flow.
(4)             Returns
(4)             -------
(4)             flow_value : integer, float
(8)                 Value of the maximum flow, i.e., net outflow from the source.
(4)             Raises
(4)             ------
(4)             NetworkXError
(8)                 The algorithm does not support MultiGraph and MultiDiGraph. If
(8)                 the input graph is an instance of one of these two classes, a
(8)                 NetworkXError is raised.
(4)             NetworkXUnbounded
(8)                 If the graph has a path of infinite capacity, the value of a
(8)                 feasible flow on the graph is unbounded above and the function
(8)                 raises a NetworkXUnbounded.

(4)             :meth:`shortest_augmenting_path`
(4)             Notes
(4)             -----
(4)             The function used in the flow_func parameter has to return a residual
(4)             network that follows NetworkX conventions:
(4)             The residual network :samp:`R` from an input graph :samp:`G` has the
(4)             same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
(4)             of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
(4)             self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
(4)             in :samp:`G`.
(4)             For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
(4)             is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
(4)             in :samp:`G` or zero otherwise. If the capacity is infinite,
(4)             :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
(4)             that does not affect the solution of the problem. This value is stored in
(4)             :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
(4)             :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
(4)             satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
(4)             The flow value, defined as the total flow into :samp:`t`, the sink, is
(4)             stored in :samp:`R.graph['flow_value']`. Reachability to :samp:`t` using
(4)             only edges :samp:`(u, v)` such that
(4)             :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
(4)             :samp:`s`-:samp:`t` cut.
(4)             Specific algorithms may store extra data in :samp:`R`.
(4)             The function should supports an optional boolean parameter value_only.
When
(4)             True, it can optionally terminate the algorithm as soon as the maximum
flow
(4)             value and the minimum cut can be determined.
(4)             Examples
(4)             --------
(4)             >>> G = nx.DiGraph()
(4)             >>> G.add_edge("x", "a", capacity=3.0)
(4)             >>> G.add_edge("x", "b", capacity=1.0)
(4)             >>> G.add_edge("a", "c", capacity=3.0)
(4)             >>> G.add_edge("b", "c", capacity=5.0)
(4)             >>> G.add_edge("b", "d", capacity=4.0)
(4)             >>> G.add_edge("d", "e", capacity=2.0)
```

```
(4)                 >>> G.add_edge("c", "y", capacity=2.0)
(4)                 >>> G.add_edge("e", "y", capacity=3.0)
(4)                 maximum_flow_value computes only the value of the
(4)                 maximum flow:
(4)                 >>> flow_value = nx.maximum_flow_value(G, "x", "y")
(4)                 >>> flow_value
(4)                 3.0
(4)                 You can also use alternative algorithms for computing the
(4)                 maximum flow by using the flow_func parameter.
(4)                 >>> from networkx.algorithms.flow import shortest_augmenting_path
(4)                 >>> flow_value == nx.maximum_flow_value(G, "x", "y",
flow_func=shortest_augmenting_path)
(4)                 True
(4)                 """
(4)                 if flow_func is None:
(8)                     if kwargs:
(12)                        raise nx.NetworkXError(

(4)                 Use the max-flow min-cut theorem, i.e., the capacity of a minimum
(4)                 capacity cut is equal to the flow value of a maximum flow.
(4)                 Parameters
(4)                 ----------
(4)                 flowG : NetworkX graph
(8)                     Edges of the graph are expected to have an attribute called
(8)                     'capacity'. If this attribute is not present, the edge is
(8)                     considered to have infinite capacity.
(4)                 _s : node
(8)                     Source node for the flow.
(4)                 _t : node
(8)                     Sink node for the flow.
(4)                 capacity : string
(8)                     Edges of the graph G are expected to have an attribute capacity
(8)                     that indicates how much flow the edge can support. If this
(8)                     attribute is not present, the edge is considered to have
(8)                     infinite capacity. Default value: 'capacity'.
(4)                 flow_func : function
(8)                     A function for computing the maximum flow among a pair of nodes
(8)                     in a capacitated graph. The function has to accept at least three
(8)                     parameters: a Graph or Digraph, a source node, and a target node.
(8)                     And return a residual network that follows NetworkX conventions
(8)                     (see Notes). If flow_func is None, the default maximum
(8)                     flow function (:meth:`preflow_push`) is used. See below for
(8)                     alternative algorithms. The choice of the default function may change
(8)                     from version to version and should not be relied on. Default value:
(8)                     None.
(4)                 kwargs : Any other keyword parameter is passed to the function that
(8)                     computes the maximum flow.
(4)                 Returns
(4)                 -------
(4)                 cut_value : integer, float
(8)                     Value of the minimum cut.
(4)                 Raises
(4)                 ------
(4)                 NetworkXUnbounded
(8)                     If the graph has a path of infinite capacity, all cuts have
(8)                     infinite capacity and the function raises a NetworkXError.
(4)                 See also

(4)                 Notes
```

```
418: (4)                -----
419: (4)                The function used in the flow_func parameter has to return a residual
420: (4)                network that follows NetworkX conventions:
421: (4)                The residual network :samp:`R` from an input graph :samp:`G` has the
422: (4)                same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
423: (4)                of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
424: (4)                self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
425: (4)                in :samp:`G`.
426: (4)                For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
427: (4)                is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
428: (4)                in :samp:`G` or zero otherwise. If the capacity is infinite,
429: (4)                :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
430: (4)                that does not affect the solution of the problem. This value is stored in
431: (4)                :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
432: (4)                :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
433: (4)                satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
434: (4)                The flow value, defined as the total flow into :samp:`t`, the sink, is
435: (4)                stored in :samp:`R.graph['flow_value']`. Reachability to :samp:`t` using
436: (4)                only edges :samp:`(u, v)` such that
437: (4)                :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
438: (4)                :samp:`s`-:samp:`t` cut.
439: (4)                Specific algorithms may store extra data in :samp:`R`.
440: (4)                The function should supports an optional boolean parameter value_only.
When
441: (4)                True, it can optionally terminate the algorithm as soon as the maximum
flow
442: (4)                value and the minimum cut can be determined.
443: (4)                Examples
444: (4)                --------
445: (4)                >>> G = nx.DiGraph()
446: (4)                >>> G.add_edge("x", "a", capacity=3.0)
447: (4)                >>> G.add_edge("x", "b", capacity=1.0)
448: (4)                >>> G.add_edge("a", "c", capacity=3.0)
449: (4)                >>> G.add_edge("b", "c", capacity=5.0)
450: (4)                >>> G.add_edge("b", "d", capacity=4.0)
451: (4)                >>> G.add_edge("d", "e", capacity=2.0)
452: (4)                >>> G.add_edge("c", "y", capacity=2.0)
453: (4)                >>> G.add_edge("e", "y", capacity=3.0)
454: (4)                minimum_cut_value computes only the value of the
455: (4)                minimum cut:
456: (4)                >>> cut_value = nx.minimum_cut_value(G, "x", "y")
457: (4)                >>> cut_value
458: (4)                3.0
459: (4)                You can also use alternative algorithms for computing the
460: (4)                minimum cut by using the flow_func parameter.
461: (4)                >>> from networkx.algorithms.flow import shortest_augmenting_path
462: (4)                >>> cut_value == nx.minimum_cut_value(G, "x", "y",

14: (4)                 A Gomory-Hu tree of an undirected graph with capacities is a
15: (4)                 weighted tree that represents the minimum s-t cuts for all s-t
16: (4)                 pairs in the graph.
17: (4)                 It only requires `n-1` minimum cut computations instead of the
18: (4)                 obvious `n(n-1)/2`. The tree represents all s-t cuts as the
19: (4)                 minimum cut value among any pair of nodes is the minimum edge
20: (4)                 weight in the shortest path between the two nodes in the
21: (4)                 Gomory-Hu tree.
22: (4)                 The Gomory-Hu tree also has the property that removing the
23: (4)                 edge with the minimum weight in the shortest path between
24: (4)                 any two nodes leaves two connected components that form
25: (4)                 a partition of the nodes in G that defines the minimum s-t
26: (4)                 cut.
27: (4)                 See Examples section below for details.
28: (4)                 Parameters
29: (4)                 ----------
30: (4)                 G : NetworkX graph
31: (8)                     Undirected graph
32: (4)                 capacity : string
33: (8)                     Edges of the graph G are expected to have an attribute capacity
34: (8)                     that indicates how much flow the edge can support. If this
35: (8)                     attribute is not present, the edge is considered to have
36: (8)                     infinite capacity. Default value: 'capacity'.
37: (4)                 flow_func : function
38: (8)                     Function to perform the underlying flow computations. Default value
39: (8)                     :func:`edmonds_karp`. This function performs better in sparse graphs
40: (8)                     with right tailed degree distributions.
41: (8)                     :func:`shortest_augmenting_path` will perform better in denser
42: (8)                     graphs.
43: (4)                 Returns
44: (4)                 -------
45: (4)                 Tree : NetworkX graph
46: (8)                     A NetworkX graph representing the Gomory-Hu tree of the input graph.
47: (4)                 Raises
48: (4)                 ------
49: (4)                 NetworkXNotImplemented
50: (8)                     Raised if the input graph is directed.
51: (4)                 NetworkXError
52: (8)                     Raised if the input graph is an empty Graph.
53: (4)                 Examples
54: (4)                 --------

(4)     >>> T.remove_edge(*edge)
(4)     >>> U, V = list(nx.connected_components(T))
(4)     >>> # Thus U and V form a partition that defines a minimum cut
(4)     ... # between u and v in G. You can compute the edge cut set,
(4)     ... # that is, the set of edges that if removed from G will
(4)     ... # disconnect u from v in G, with this information:
(4)     ... cutset = set()
(4)     >>> for x, nbrs in ((n, G[n]) for n in U):
(4)     ...     cutset.update((x, y) for y in nbrs if y in V)
(4)     >>> # Because we have set the capacities of all edges to 1
(4)     ... # the cutset contains ten edges
(4)     ... len(cutset)
(4)     10
(4)     >>> # You can use any maximum flow algorithm for the underlying
(4)     ... # flow computations using the argument flow_func
(4)     ... from networkx.algorithms import flow
(4)     >>> T = nx.gomory_hu_tree(G, flow_func=flow.boykov_kolmogorov)
(4)     >>> cut_value, edge = minimum_edge_weight_in_shortest_path(T, u, v)
(4)     >>> cut_value
(4)     10
(4)     >>> nx.minimum_cut_value(G, u, v, flow_func=flow.boykov_kolmogorov)
(4)     10
(4)     Notes
(4)     -----
(4)     This implementation is based on Gusfield approach [1]_ to compute
(4)     Gomory-Hu trees, which does not require node contractions and has
(4)     the same computational complexity than the original method.

186: (4)                Notes
187: (4)                -----
188: (4)                This algorithm is not guaranteed to work if edge weights or demands
189: (4)                are floating point numbers (overflows and roundoff errors can
190: (4)                cause problems). As a workaround you can use integer numbers by
```

```
(4)                 multiplying the relevant edge attributes by a convenient
(4)                 constant factor (eg 100).
(4)                 Examples
(4)                 --------
(4)                 >>> G = nx.DiGraph()
(4)                 >>> G.add_node("a", demand=-5)
(4)                 >>> G.add_node("d", demand=5)
(4)                 >>> G.add_edge("a", "b", weight=3, capacity=4)
(4)                 >>> G.add_edge("a", "c", weight=6, capacity=10)
(4)                 >>> G.add_edge("b", "d", weight=1, capacity=9)
(4)                 >>> G.add_edge("c", "d", weight=2, capacity=5)
(4)                 >>> flowDict = nx.min_cost_flow(G)
(4)                 >>> flowDict
(4)                 {'a': {'b': 4, 'c': 1}, 'd': {}, 'b': {'d': 4}, 'c': {'d': 1}}
(4)                 >>> nx.cost_of_flow(G, flowDict)
(4)                 24
(4)                 """
(4)                 return sum((flowDict[u][v] * d.get(weight, 0) for u, v, d in
G.edges(data=True)))
(0)             @nx._dispatchable(edge_attrs={"capacity": float("inf"), "weight": 0})
(0)             def max_flow_min_cost(G, s, t, capacity="capacity", weight="weight"):
(4)                 """Returns a maximum (s, t)-flow of minimum cost.
(4)                 G is a digraph with edge costs and capacities. There is a source
(4)                 node s and a sink node t. This function finds a maximum flow from
(4)                 s to t whose total cost is minimized.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(8)                     DiGraph on which a minimum cost flow satisfying all demands is
(8)                     to be found.
(4)                 s: node label
(8)                     Source of the flow.
(4)                 t: node label
(8)                     Destination of the flow.
(4)                 capacity: string
(8)                     Edges of the graph G are expected to have an attribute capacity
(8)                     that indicates how much flow the edge can support. If this
(8)                     attribute is not present, the edge is considered to have
(8)                     infinite capacity. Default value: 'capacity'.
(4)                 weight: string
(8)                     Edges of the graph G are expected to have an attribute weight
(8)                     that indicates the cost incurred by sending one unit of flow on
(8)                     that edge. If not present, the weight is considered to be 0.
(8)                     Default value: 'weight'.
(4)                 Returns
(4)                 -------
(4)                 flowDict: dictionary
(8)                     Dictionary of dictionaries keyed by nodes such that
(8)                     flowDict[u][v] is the flow edge (u, v).
(4)                 Raises
(4)                 ------
(4)                 NetworkXError
(8)                     This exception is raised if the input graph is not directed or
(8)                     not connected.
(4)                 NetworkXUnbounded
(8)                     This exception is raised if there is an infinite capacity path
(8)                     from s to t in G. In this case there is no maximum flow. This
(8)                     exception is also raised if the digraph G has a cycle of
(8)                     negative cost and infinite capacity. Then, the cost of a flow
(8)                     is unbounded below.

281: (4)                This is a primal network simplex algorithm that uses the leaving
282: (4)                arc rule to prevent cycling.
283: (4)                G is a digraph with edge costs and capacities and in which nodes
284: (4)                have demand, i.e., they want to send or receive some amount of
285: (4)                flow. A negative demand means that the node wants to send flow, a
286: (4)                positive demand means that the node want to receive flow. A flow on
287: (4)                the digraph G satisfies all demand if the net flow into each node
```

```
    (4)                 is equal to the demand of that node.
    (4)                 Parameters
    (4)                 ----------
    (4)                 G : NetworkX graph
    (8)                     DiGraph on which a minimum cost flow satisfying all demands is
    (8)                     to be found.
    (4)                 demand : string
    (8)                     Nodes of the graph G are expected to have an attribute demand
    (8)                     that indicates how much flow a node wants to send (negative
    (8)                     demand) or receive (positive demand). Note that the sum of the
    (8)                     demands should be 0 otherwise the problem in not feasible. If
    (8)                     this attribute is not present, a node is considered to have 0
    (8)                     demand. Default value: 'demand'.
    (4)                 capacity : string
    (8)                     Edges of the graph G are expected to have an attribute capacity
    (8)                     that indicates how much flow the edge can support. If this
    (8)                     attribute is not present, the edge is considered to have
    (8)                     infinite capacity. Default value: 'capacity'.
    (4)                 weight : string
    (8)                     Edges of the graph G are expected to have an attribute weight
    (8)                     that indicates the cost incurred by sending one unit of flow on
    (8)                     that edge. If not present, the weight is considered to be 0.
    (8)                     Default value: 'weight'.
    (4)                 Returns
    (4)                 -------
    (4)                 flowCost : integer, float
    (8)                     Cost of a minimum cost flow satisfying all demands.
    (4)                 flowDict : dictionary
    (8)                     Dictionary of dictionaries keyed by nodes such that
    (8)                     flowDict[u][v] is the flow edge (u, v).
    (4)                 Raises
    (4)                 ------
    (4)                 NetworkXError
    (8)                     This exception is raised if the input graph is not directed or
    (8)                     not connected.
    (4)                 NetworkXUnfeasible
    (8)                     This exception is raised in the following situations:
    (12)                        * The sum of the demands is not zero. Then, there is no
    (14)                          flow satisfying all demands.
    (12)                        * There is no flow satisfying all demand.
    (4)                 NetworkXUnbounded
    (8)                     This exception is raised if the digraph G has a cycle of
    (8)                     negative cost and infinite capacity. Then, the cost of a flow
    (8)                     satisfying all demands is unbounded below.
    (4)                 Notes
    (4)                 -----
    (4)                 This algorithm is not guaranteed to work if edge weights or demands
    (4)                 are floating point numbers (overflows and roundoff errors can
    (4)                 cause problems). As a workaround you can use integer numbers by
    (4)                 multiplying the relevant edge attributes by a convenient
    (4)                 constant factor (eg 100).

    (4)                 Examples
    (4)                 --------
    (4)                 A simple example of a min cost flow problem.
    (4)                 >>> G = nx.DiGraph()
    (4)                 >>> G.add_node("a", demand=-5)
    (4)                 >>> G.add_node("d", demand=5)
    (4)                 >>> G.add_edge("a", "b", weight=3, capacity=4)
    (4)                 >>> G.add_edge("a", "c", weight=6, capacity=10)
    (4)                 >>> G.add_edge("b", "d", weight=1, capacity=9)
    (4)                 >>> G.add_edge("c", "d", weight=2, capacity=5)
    (4)                 >>> flowCost, flowDict = nx.network_simplex(G)
    (4)                 >>> flowCost
    (4)                 24
    (4)                 >>> flowDict
    (4)                 {'a': {'b': 4, 'c': 1}, 'd': {}, 'b': {'d': 4}, 'c': {'d': 1}}
```

```
(4)                 The mincost flow algorithm can also be used to solve shortest path
(4)                 problems. To find the shortest path between two nodes u and v,
(4)                 give all edges an infinite capacity, give node u a demand of -1 and
(4)                 node v a demand a 1. Then run the network simplex. The value of a
(4)                 min cost flow will be the distance between u and v and edges
(4)                 carrying positive flow will indicate the path.
(4)                 >>> G = nx.DiGraph()
(4)                 >>> G.add_weighted_edges_from(
(4)                 ...     [
(4)                 ...         ("s", "u", 10),
(4)                 ...         ("s", "x", 5),
(4)                 ...         ("u", "v", 1),
(4)                 ...         ("u", "x", 2),
(4)                 ...         ("v", "y", 1),

216: (4)                $m$ edges.
```

```
    Parameters
    ----------
    G : NetworkX graph
        Edges of the graph are expected to have an attribute called
        'capacity'. If this attribute is not present, the edge is
        considered to have infinite capacity.
    s : node
        Source node for the flow.
    t : node
        Sink node for the flow.
    capacity : string
        Edges of the graph G are expected to have an attribute capacity
        that indicates how much flow the edge can support. If this
        attribute is not present, the edge is considered to have
        infinite capacity. Default value: 'capacity'.
    residual : NetworkX graph
        Residual network on which the algorithm is to be executed. If None, a
        new residual network is created. Default value: None.
    global_relabel_freq : integer, float
        Relative frequency of applying the global relabeling heuristic to
speed

        up the algorithm. If it is None, the heuristic is disabled. Default
        value: 1.
    value_only : bool
        If False, compute a maximum flow; otherwise, compute a maximum preflow
        which is enough for computing the maximum flow value. Default value:
        False.
    Returns
    -------
    R : NetworkX DiGraph
        Residual network after computing the maximum flow.
    Raises
    ------
    NetworkXError
        The algorithm does not support MultiGraph and MultiDiGraph. If
        the input graph is an instance of one of these two classes, a
        NetworkXError is raised.
    NetworkXUnbounded
        If the graph has a path of infinite capacity, the value of a
        feasible flow on the graph is unbounded above and the function
        raises a NetworkXUnbounded.

    :meth:`minimum_cut`
    :meth:`edmonds_karp`
    :meth:`shortest_augmenting_path`
    Notes
    -----
    The residual network :samp:`R` from an input graph :samp:`G` has the
    same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
    of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
    self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
    in :samp:`G`. For each node :samp:`u` in :samp:`R`,
    :samp:`R.nodes[u]['excess']` represents the difference between flow into
    :samp:`u` and flow out of :samp:`u`.
    For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
    is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
    in :samp:`G` or zero otherwise. If the capacity is infinite,
    :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
    that does not affect the solution of the problem. This value is stored in
    :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
    :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
    satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
    The flow value, defined as the total flow into :samp:`t`, the sink, is
    stored in :samp:`R.graph['flow_value']`. Reachability to :samp:`t` using
    only edges :samp:`(u, v)` such that
    :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
    :samp:`s`-:samp:`t` cut.

(4)                 r"""Find a maximum single-commodity flow using the shortest augmenting
path
(4)                 algorithm.
(4)                 This function returns the residual network resulting after computing
(4)                 the maximum flow. See below for details about the conventions
(4)                 NetworkX uses for defining residual networks.
(4)                 This algorithm has a running time of $O(n^2 m)$ for $n$ nodes and $m$
(4)                 edges.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(8)                     Edges of the graph are expected to have an attribute called
(8)                     'capacity'. If this attribute is not present, the edge is
(8)                     considered to have infinite capacity.
(4)                 s : node
(8)                     Source node for the flow.
(4)                 t : node
(8)                     Sink node for the flow.
(4)                 capacity : string
(8)                     Edges of the graph G are expected to have an attribute capacity
(8)                     that indicates how much flow the edge can support. If this
(8)                     attribute is not present, the edge is considered to have
(8)                     infinite capacity. Default value: 'capacity'.
(4)                 residual : NetworkX graph
(8)                     Residual network on which the algorithm is to be executed. If None, a
(8)                     new residual network is created. Default value: None.
(4)                 value_only : bool
(8)                     If True compute only the value of the maximum flow. This parameter
(8)                     will be ignored by this algorithm because it is not applicable.
(4)                 two_phase : bool
(8)                     If True, a two-phase variant is used. The two-phase variant improves
(8)                     the running time on unit-capacity networks from $O(nm)$ to
(8)                     $O(\min(n^{2/3}, m^{1/2}) m)$. Default value: False.
```

```
    cutoff : integer, float
        If specified, the algorithm will terminate when the flow value reaches
        or exceeds the cutoff. In this case, it may be unable to immediately
        determine a minimum cut. Default value: None.
    Returns
    -------
    R : NetworkX DiGraph
        Residual network after computing the maximum flow.
    Raises
    ------
    NetworkXError
        The algorithm does not support MultiGraph and MultiDiGraph. If
        the input graph is an instance of one of these two classes, a
        NetworkXError is raised.
    NetworkXUnbounded
        If the graph has a path of infinite capacity, the value of a
        feasible flow on the graph is unbounded above and the function
        raises a NetworkXUnbounded.

    Notes
    -----
    The residual network :samp:`R` from an input graph :samp:`G` has the
    same nodes as :samp:`G`. :samp:`R` is a DiGraph that contains a pair
    of edges :samp:`(u, v)` and :samp:`(v, u)` iff :samp:`(u, v)` is not a
    self-loop, and at least one of :samp:`(u, v)` and :samp:`(v, u)` exists
    in :samp:`G`.
    For each edge :samp:`(u, v)` in :samp:`R`, :samp:`R[u][v]['capacity']`
    is equal to the capacity of :samp:`(u, v)` in :samp:`G` if it exists
    in :samp:`G` or zero otherwise. If the capacity is infinite,
    :samp:`R[u][v]['capacity']` will have a high arbitrary finite value
    that does not affect the solution of the problem. This value is stored in
    :samp:`R.graph['inf']`. For each edge :samp:`(u, v)` in :samp:`R`,
    :samp:`R[u][v]['flow']` represents the flow function of :samp:`(u, v)` and
    satisfies :samp:`R[u][v]['flow'] == -R[v][u]['flow']`.
    The flow value, defined as the total flow into :samp:`t`, the sink, is
    stored in :samp:`R.graph['flow_value']`. If :samp:`cutoff` is not
    specified, reachability to :samp:`t` using only edges :samp:`(u, v)` such
    that :samp:`R[u][v]['flow'] < R[u][v]['capacity']` induces a minimum
    :samp:`s`-:samp:`t` cut.
    Examples
    --------
    >>> from networkx.algorithms.flow import shortest_augmenting_path
    The functions that implement flow algorithms and output a residual
    network, such as this one, are not imported to the base NetworkX
    namespace, so you have to explicitly import them from the flow package.
    >>> G = nx.DiGraph()
    >>> G.add_edge("x", "a", capacity=3.0)
    >>> G.add_edge("x", "b", capacity=1.0)
    >>> G.add_edge("a", "c", capacity=3.0)
    >>> G.add_edge("b", "c", capacity=5.0)
    >>> G.add_edge("b", "d", capacity=4.0)
    >>> G.add_edge("d", "e", capacity=2.0)
    >>> G.add_edge("c", "y", capacity=2.0)
    >>> G.add_edge("e", "y", capacity=3.0)
    >>> R = shortest_augmenting_path(G, "x", "y")

File 255 - ismags.py:

```
1: (0)              """
2: (0)              ISMAGS Algorithm
3: (0)              ================
4: (0)              Provides a Python implementation of the ISMAGS algorithm. [1]_
5: (0)              It is capable of finding (subgraph) isomorphisms between two graphs, taking
the
6: (0)              symmetry of the subgraph into account. In most cases the VF2 algorithm is
7: (0)              faster (at least on small graphs) than this implementation, but in some cases
8: (0)              there is an exponential number of isomorphisms that are symmetrically
9: (0)              equivalent. In that case, the ISMAGS algorithm will provide only one solution
10: (0)             per symmetry group.
11: (0)             >>> petersen = nx.petersen_graph()
12: (0)             >>> ismags = nx.isomorphism.ISMAGS(petersen, petersen)
13: (0)             >>> isomorphisms = list(ismags.isomorphisms_iter(symmetry=False))
14: (0)             >>> len(isomorphisms)
15: (0)             120
16: (0)             >>> isomorphisms = list(ismags.isomorphisms_iter(symmetry=True))
17: (0)             >>> answer = [{0: 0, 1: 1, 2: 2, 3: 3, 4: 4, 5: 5, 6: 6, 7: 7, 8: 8, 9: 9}]
18: (0)             >>> answer == isomorphisms
19: (0)             True
20: (0)             In addition, this implementation also provides an interface to find the
21: (0)             largest common induced subgraph [2]_ between any two graphs, again taking
22: (0)             symmetry into account. Given `graph` and `subgraph` the algorithm will remove
23: (0)             nodes from the `subgraph` until `subgraph` is isomorphic to a subgraph of
24: (0)             `graph`. Since only the symmetry of `subgraph` is taken into account it is
25: (0)             worth thinking about how you provide your graphs:
26: (0)             >>> graph1 = nx.path_graph(4)
27: (0)             >>> graph2 = nx.star_graph(3)
28: (0)             >>> ismags = nx.isomorphism.ISMAGS(graph1, graph2)
29: (0)             >>> ismags.is_isomorphic()
30: (0)             False
31: (0)             >>> largest_common_subgraph = list(ismags.largest_common_subgraph())
32: (0)             >>> answer = [{1: 0, 0: 1, 2: 2}, {2: 0, 1: 1, 3: 2}]
33: (0)             >>> answer == largest_common_subgraph
34: (0)             True
35: (0)             >>> ismags2 = nx.isomorphism.ISMAGS(graph2, graph1)
36: (0)             >>> largest_common_subgraph = list(ismags2.largest_common_subgraph())
37: (0)             >>> answer = [
38: (0)             ...     {1: 0, 0: 1, 2: 2},
39: (0)             ...     {1: 0, 0: 1, 3: 2},
40: (0)             ...     {2: 0, 0: 1, 1: 2},
41: (0)             ...     {2: 0, 0: 1, 3: 2},
42: (0)             ...     {3: 0, 0: 1, 1: 2},
43: (0)             ...     {3: 0, 0: 1, 2: 2},
44: (0)             ... ]
45: (0)             >>> answer == largest_common_subgraph
46: (0)             True
47: (0)             However, when not taking symmetry into account, it doesn't matter:
48: (0)             >>> largest_common_subgraph =
list(ismags.largest_common_subgraph(symmetry=False))
49: (0)             >>> answer = [

81: (0)             True
82: (0)             Notes
83: (0)             -----
84: (0)             - The current implementation works for undirected graphs only. The algorithm
85: (2)               in general should work for directed graphs as well though.
86: (0)             - Node keys for both provided graphs need to be fully orderable as well as
87: (2)               hashable.
88: (0)             - Node and edge equality is assumed to be transitive: if A is equal to B, and
89: (2)               B is equal to C, then A is equal to C.

otherwise.
```

```
(4)                 Parameters
(4)                 ----------
(4)                 G1, G2: graphs
(8)                     The two graphs G1 and G2 must be the same type.
(4)                 node_match : callable
(8)                     A function that returns True if node n1 in G1 and n2 in G2 should
(8)                     be considered equal during the isomorphism test.
(8)                     If node_match is not specified then node attributes are not
considered.
(8)                     The function will be called like
(11)                       node_match(G1.nodes[n1], G2.nodes[n2]).
(8)                     That is, the function will receive the node attribute dictionaries
(8)                     for n1 and n2 as inputs.
(4)                 edge_match : callable
(8)                     A function that returns True if the edge attribute dictionary
(8)                     for the pair of nodes (u1, v1) in G1 and (u2, v2) in G2 should
(8)                     be considered equal during the isomorphism test.  If edge_match is
(8)                     not specified then edge attributes are not considered.
(8)                     The function will be called like
(11)                       edge_match(G1[u1][v1], G2[u2][v2]).
(8)                     That is, the function will receive the edge attribute dictionaries
(8)                     of the edges under consideration.

2: (0)              *************
3: (0)              VF2 Algorithm
4: (0)              *************
5: (0)              An implementation of VF2 algorithm for graph isomorphism testing.
6: (0)              The simplest interface to use this module is to call the
7: (0)              :func:`is_isomorphic <networkx.algorithms.isomorphism.is_isomorphic>`
8: (0)              function.
9: (0)              Introduction
10: (0)             ------------
11: (0)             The GraphMatcher and DiGraphMatcher are responsible for matching
12: (0)             graphs or directed graphs in a predetermined manner.  This
13: (0)             usually means a check for an isomorphism, though other checks
14: (0)             are also possible.  For example, a subgraph of one graph
15: (0)             can be checked for isomorphism to a second graph.
16: (0)             Matching is done via syntactic feasibility. It is also possible
17: (0)             to check for semantic feasibility. Feasibility, then, is defined
18: (0)             as the logical AND of the two functions.
19: (0)             To include a semantic check, the (Di)GraphMatcher class should be
20: (0)             subclassed, and the
21: (0)             :meth:`semantic_feasibility
<networkx.algorithms.isomorphism.GraphMatcher.semantic_feasibility>`
22: (0)             function should be redefined.  By default, the semantic feasibility function
always
23: (0)             returns ``True``.  The effect of this is that semantics are not
24: (0)             considered in the matching of G1 and G2.
25: (0)             Examples
26: (0)             --------
27: (0)             Suppose G1 and G2 are isomorphic graphs. Verification is as follows:
28: (0)             >>> from networkx.algorithms import isomorphism
29: (0)             >>> G1 = nx.path_graph(4)
30: (0)             >>> G2 = nx.path_graph(4)
31: (0)             >>> GM = isomorphism.GraphMatcher(G1, G2)
32: (0)             >>> GM.is_isomorphic()
33: (0)             True
34: (0)             GM.mapping stores the isomorphism mapping from G1 to G2.
35: (0)             >>> GM.mapping
36: (0)             {0: 0, 1: 1, 2: 2, 3: 3}
37: (0)             Suppose G1 and G2 are isomorphic directed graphs.
38: (0)             Verification is as follows:
39: (0)             >>> G1 = nx.path_graph(4, create_using=nx.DiGraph())
40: (0)             >>> G2 = nx.path_graph(4, create_using=nx.DiGraph())
41: (0)             >>> DiGM = isomorphism.DiGraphMatcher(G1, G2)
42: (0)             >>> DiGM.is_isomorphic()
43: (0)             True
44: (0)             DiGM.mapping stores the isomorphism mapping from G1 to G2.
45: (0)             >>> DiGM.mapping
46: (0)             {0: 0, 1: 1, 2: 2, 3: 3}
```

```
47: (0)             Subgraph Isomorphism
48: (0)             --------------------
49: (0)             Graph theory literature can be ambiguous about the meaning of the
50: (0)             above statement, and we seek to clarify it now.
51: (0)             In the VF2 literature, a mapping `M` is said to be a graph-subgraph
52: (0)             isomorphism iff `M` is an isomorphism between `G2` and a subgraph of `G1`.
53: (0)             Thus, to say that `G1` and `G2` are graph-subgraph isomorphic is to say
54: (0)             that a subgraph of `G1` is isomorphic to `G2`.
55: (0)             Other literature uses the phrase 'subgraph isomorphic' as in '`G1` does
56: (0)             not have a subgraph isomorphic to `G2`'.  Another use is as an in adverb
57: (0)             for isomorphic.  Thus, to say that `G1` and `G2` are subgraph isomorphic
58: (0)             is to say that a subgraph of `G1` is isomorphic to `G2`.
59: (0)             Finally, the term 'subgraph' can have multiple meanings. In this
60: (0)             context, 'subgraph' always means a 'node-induced subgraph'. Edge-induced
61: (0)             subgraph isomorphisms are not directly supported, but one should be
62: (0)             able to perform the check by making use of
63: (0)             :func:`line_graph <networkx.generators.line.line_graph>`. For
64: (0)             subgraphs which are not induced, the term 'monomorphism' is preferred
65: (0)             over 'isomorphism'.
66: (0)             Let ``G = (N, E)`` be a graph with a set of nodes `N` and set of edges `E`.
67: (0)             If ``G' = (N', E')`` is a subgraph, then:
68: (4)                 `N'` is a subset of `N` and
69: (4)                 `E'` is a subset of `E`.
70: (0)             If ``G' = (N', E')`` is a node-induced subgraph, then:
71: (4)                 `N'` is a subset of `N` and
72: (4)                 `E'` is the subset of edges in `E` relating nodes in `N'`.
73: (0)             If `G' = (N', E')` is an edge-induced subgraph, then:
74: (4)                 `N'` is the subset of nodes in `N` related by edges in `E'` and
75: (4)                 `E'` is a subset of `E`.
76: (0)             If `G' = (N', E')` is a monomorphism, then:
77: (4)                 `N'` is a subset of `N` and
78: (4)                 `E'` is a subset of the set of edges in `E` relating nodes in `N'`.
79: (0)             Note that if `G'` is a node-induced subgraph of `G`, then it is always a
80: (0)             subgraph monomorphism of `G`, but the opposite is not always true, as a
81: (0)             monomorphism can have fewer edges.

```
1: (0)              """
2: (0)              ****************************
3: (0)              Time-respecting VF2 Algorithm
4: (0)              ****************************
5: (0)              An extension of the VF2 algorithm for time-respecting graph isomorphism
6: (0)              testing in temporal graphs.
7: (0)              A temporal graph is one in which edges contain a datetime attribute,
8: (0)              denoting when interaction occurred between the incident nodes. A
9: (0)              time-respecting subgraph of a temporal graph is a subgraph such that
10: (0)             all interactions incident to a node occurred within a time threshold,
11: (0)             delta, of each other. A directed time-respecting subgraph has the
12: (0)             added constraint that incoming interactions to a node must precede
13: (0)             outgoing interactions from the same node - this enforces a sense of
14: (0)             directed flow.
15: (0)             Introduction
16: (0)             ------------
17: (0)             The TimeRespectingGraphMatcher and TimeRespectingDiGraphMatcher
18: (0)             extend the GraphMatcher and DiGraphMatcher classes, respectively,
19: (0)             to include temporal constraints on matches. This is achieved through
20: (0)             a semantic check, via the semantic_feasibility() function.
21: (0)             As well as including G1 (the graph in which to seek embeddings) and
```

```
22: (0)             G2 (the subgraph structure of interest), the name of the temporal
23: (0)             attribute on the edges and the time threshold, delta, must be supplied
24: (0)             as arguments to the matching constructors.
25: (0)             A delta of zero is the strictest temporal constraint on the match -
26: (0)             only embeddings in which all interactions occur at the same time will
27: (0)             be returned. A delta of one day will allow embeddings in which
28: (0)             adjacent interactions occur up to a day apart.
29: (0)             Examples
30: (0)             --------
31: (0)             Examples will be provided when the datetime type has been incorporated.
32: (0)             Temporal Subgraph Isomorphism
33: (0)             ----------------------------
34: (0)             A brief discussion of the somewhat diverse current literature will be
35: (0)             included here.

```
1: (0)              """
2: (0)              ***************
3: (0)              VF2++ Algorithm
4: (0)              ***************
5: (0)              An implementation of the VF2++ algorithm [1]_ for Graph Isomorphism testing.
6: (0)              The simplest interface to use this module is to call:
7: (0)              `vf2pp_is_isomorphic`: to check whether two graphs are isomorphic.
8: (0)              `vf2pp_isomorphism`: to obtain the node mapping between two graphs,
9: (0)              in case they are isomorphic.
10: (0)             `vf2pp_all_isomorphisms`: to generate all possible mappings between two
graphs,
11: (0)             if isomorphic.
12: (0)             Introduction
13: (0)             ------------
14: (0)             The VF2++ algorithm, follows a similar logic to that of VF2, while also
15: (0)             introducing new easy-to-check cutting rules and determining the optimal access
16: (0)             order of nodes. It is also implemented in a non-recursive manner, which saves
17: (0)             both time and space, when compared to its previous counterpart.
18: (0)             The optimal node ordering is obtained after taking into consideration both the
19: (0)             degree but also the label rarity of each node.
20: (0)             This way we place the nodes that are more likely to match, first in the order,
21: (0)             thus examining the most promising branches in the beginning.
22: (0)             The rules also consider node labels, making it easier to prune unfruitful
23: (0)             branches early in the process.
24: (0)             Examples
25: (0)             --------
26: (0)             Suppose G1 and G2 are Isomorphic Graphs. Verification is as follows:
27: (0)             Without node labels:
28: (0)             >>> import networkx as nx
29: (0)             >>> G1 = nx.path_graph(4)
30: (0)             >>> G2 = nx.path_graph(4)
```

```
31: (0)             >>> nx.vf2pp_is_isomorphic(G1, G2, node_label=None)
32: (0)             True
33: (0)             >>> nx.vf2pp_isomorphism(G1, G2, node_label=None)
34: (0)             {1: 1, 2: 2, 0: 0, 3: 3}
35: (0)             With node labels:
36: (0)             >>> G1 = nx.path_graph(4)
37: (0)             >>> G2 = nx.path_graph(4)
38: (0)             >>> mapped = {1: 1, 2: 2, 3: 3, 0: 0}
39: (0)             >>> nx.set_node_attributes(G1, dict(zip(G1, ["blue", "red", "green",
"yellow"])), "label")
40: (0)             >>> nx.set_node_attributes(G2, dict(zip([mapped[u] for u in G1], ["blue",
"red", "green", "yellow"])), "label")
41: (0)             >>> nx.vf2pp_is_isomorphic(G1, G2, node_label="label")
42: (0)             True
43: (0)             >>> nx.vf2pp_isomorphism(G1, G2, node_label="label")
44: (0)             {1: 1, 2: 2, 0: 0, 3: 3}

    Notes
    -----
    This function should be called right after the feasibility checks are passed, and node1 is mapped to node2. The
    purpose of this function is to avoid brute force computing of Ti/Ti_out by iterating over all nodes of the graph
    and checking which nodes satisfy the necessary conditions. Instead, in every step of the algorithm we focus
    exclusively on the two nodes that are being added to the mapping, incrementally updating Ti/Ti_out.
    Parameters
    ----------
    new_node1, new_node2: Graph node
        The two new nodes, added to the mapping.
    graph_params: namedtuple
        Contains all the Graph-related parameters:
        G1,G2: NetworkX Graph or MultiGraph instances.
            The two graphs to check for isomorphism or monomorphism
        G1_labels,G2_labels: dict
            The label of every node in G1 and G2 respectively
    state_params: namedtuple
        Contains all the State-related parameters:
        mapping: dict
            The mapping as extended so far. Maps nodes of G1 to nodes of G2
        reverse_mapping: dict
            The reverse mapping as extended so far. Maps nodes from G2 to nodes of G1. It's basically "mapping" reversed
        T1, T2: set
            Ti contains uncovered neighbors of covered nodes from Gi, i.e. nodes that are not in the mapping, but are
            neighbors of nodes that are.

(4)                 """
(4)                 Given two rooted trees `t1` and `t2`,
(4)                 with roots `root1` and `root2` respectively
(4)                 this routine will determine if they are isomorphic.
(4)                 These trees may be either directed or undirected,
(4)                 but if they are directed, all edges should flow from the root.
(4)                 It returns the isomorphism, a mapping of the nodes of `t1` onto the nodes
(4)                 of `t2`, such that two trees are then identical.
(4)                 Note that two trees may have more than one isomorphism, and this
(4)                 routine just returns one valid mapping.
(4)                 Parameters
(4)                 ----------
(4)                 `t1` :  NetworkX graph
(8)                     One of the trees being compared
(4)                 `root1` : a node of `t1` which is the root of the tree
(4)                 `t2` : undirected NetworkX graph
(8)                     The other tree being compared

```
1: (0)              """
2: (4)                  Module to simplify the specification of user-defined equality functions
for
3: (4)                  node and edge attributes during isomorphism checks.
4: (4)                  During the construction of an isomorphism, the algorithm considers two
5: (4)                  candidate nodes n1 in G1 and n2 in G2.  The graphs G1 and G2 are then
6: (4)                  compared with respect to properties involving n1 and n2, and if the
outcome
7: (4)                  is good, then the candidate nodes are considered isomorphic. NetworkX
8: (4)                  provides a simple mechanism for users to extend the comparisons to include
9: (4)                  node and edge attributes.
10: (4)                 Node attributes are handled by the node_match keyword. When considering
11: (4)                 n1 and n2, the algorithm passes their node attribute dictionaries to
12: (4)                 node_match, and if it returns False, then n1 and n2 cannot be
13: (4)                 considered to be isomorphic.
14: (4)                 Edge attributes are handled by the edge_match keyword. When considering
15: (4)                 n1 and n2, the algorithm must verify that outgoing edges from n1 are
16: (4)                 commensurate with the outgoing edges for n2. If the graph is directed,
17: (4)                 then a similar check is also performed for incoming edges.
18: (4)                 Focusing only on outgoing edges, we consider pairs of nodes (n1, v1) from
19: (4)                 G1 and (n2, v2) from G2. For graphs and digraphs, there is only one edge
20: (4)                 between (n1, v1) and only one edge between (n2, v2). Those edge attribute
21: (4)                 dictionaries are passed to edge_match, and if it returns False, then
22: (4)                 n1 and n2 cannot be considered isomorphic. For multigraphs and
23: (4)                 multidigraphs, there can be multiple edges between (n1, v1) and also
24: (4)                 multiple edges between (n2, v2).  Now, there must exist an isomorphism
25: (4)                 from "all the edges between (n1, v1)" to "all the edges between (n2, v2)".
26: (4)                 So, all of the edge attribute dictionaries are passed to edge_match, and
27: (4)                 it must determine if there is an isomorphism between the two sets of
edges.

203: (4)                Returns
204: (4)                -------
205: (4)                (hubs,authorities) : two-tuple of dictionaries
```

```
   Two dictionaries keyed by node containing the hub and authority
   values.
Examples
--------
>>> from networkx.algorithms.link_analysis.hits_alg import _hits_scipy
>>> G = nx.path_graph(4)
>>> h, a = _hits_scipy(G)
Notes
-----
This implementation uses SciPy sparse matrices.
The eigenvector calculation is done by the power iteration method
and has no guarantee of convergence.  The iteration will stop
after max_iter iterations or an error tolerance of
number_of_nodes(G)*tol has been reached.
The HITS algorithm was designed for directed graphs but this
algorithm does not check if the input graph is directed and will
execute on undirected graphs.
Raises
------
PowerIterationFailedConvergence
    If the algorithm fails to converge to the specified tolerance
    within the specified number of iterations of the power iteration
    method.

(6)                    Starting value of PageRank iteration for each node.
(4)                  weight : key, optional
(6)                    Edge data key to use as weight.  If None weights are set to 1.
(4)                  dangling: dict, optional
(6)                    The outedges to be assigned to any "dangling" nodes, i.e., nodes without
(6)                    any outedges. The dict key is the node the outedge points to and the
dict
(6)                    value is the weight of that outedge. By default, dangling nodes are
given
(6)                    outedges according to the personalization vector (uniform if not
(6)                    specified). This must be selected to result in an irreducible transition
(6)                    matrix (see notes under google_matrix). It may be common to have the
(6)                    dangling dict to be the same as the personalization dict.
(4)                  Returns
(4)                  -------
(4)                  pagerank : dictionary
(7)                     Dictionary of nodes with PageRank as value
(4)                  Examples
(4)                  --------
(4)                  >>> G = nx.DiGraph(nx.path_graph(4))
(4)                  >>> pr = nx.pagerank(G, alpha=0.9)
(4)                  Notes
(4)                  -----
(4)                  The eigenvector calculation is done by the power iteration method
(4)                  and has no guarantee of convergence.  The iteration will stop after
(4)                  an error tolerance of ``len(G) * tol`` has been reached. If the
(4)                  number of iterations exceed `max_iter`, a
(4)                  :exc:`networkx.exception.PowerIterationFailedConvergence` exception
(4)                  is raised.
(4)                  The PageRank algorithm was designed for directed graphs but this
```

```
    algorithm does not check if the input graph is directed and will
    execute on undirected graphs by converting each edge in the
    directed graph to two edges.
    See Also
    --------
    google_matrix
    Raises
    ------
    PowerIterationFailedConvergence
        If the algorithm fails to converge to the specified tolerance
        within the specified number of iterations of the power iteration
        method.

(4)                Parameters
(4)                ----------
(4)                G : graph
(6)                  A NetworkX graph.  Undirected graphs will be converted to a directed
(6)                  graph with two directed edges for each undirected edge.
(4)                alpha : float
(6)                  The damping factor.
(4)                personalization: dict, optional
(6)                  The "personalization vector" consisting of a dictionary with a
(6)                  key some subset of graph nodes and personalization value each of those.
(6)                  At least one personalization value must be non-zero.
(6)                  If not specified, a nodes personalization value will be zero.
(6)                  By default, a uniform distribution is used.
(4)                nodelist : list, optional
(6)                  The rows and columns are ordered according to the nodes in nodelist.
(6)                  If nodelist is None, then the ordering is produced by G.nodes().
(4)                weight : key, optional
(6)                  Edge data key to use as weight.  If None weights are set to 1.
(4)                dangling: dict, optional
(6)                  The outedges to be assigned to any "dangling" nodes, i.e., nodes without
(6)                  any outedges. The dict key is the node the outedge points to and the dict
(6)                  value is the weight of that outedge. By default, dangling nodes are given
(6)                  outedges according to the personalization vector (uniform if not
(6)                  specified) This must be selected to result in an irreducible transition
(6)                  matrix (see notes below). It may be common to have the dangling dict to
(6)                  be the same as the personalization dict.
(4)                Returns
(4)                -------
(4)                A : 2D NumPy ndarray
(7)                   Google matrix of the graph
(4)                Notes
(4)                -----
(4)                The array returned represents the transition matrix that describes the
(4)                Markov chain used in PageRank. For PageRank to converge to a unique
(4)                solution (i.e., a unique stationary distribution in a Markov chain), the
(4)                transition matrix must be irreducible. In other words, it must be that
(4)                there exists a path between every pair of nodes in the graph, or else there
(4)                is the potential of "rank sinks."
(4)                This implementation works with Multi(Di)Graphs. For multigraphs the
(4)                weight between two nodes is set to be the sum of all edge weights
(4)                between those nodes.

317: (6)                  outedges according to the personalization vector (uniform if not
318: (6)                  specified) This must be selected to result in an irreducible transition
319: (6)                  matrix (see notes under google_matrix). It may be common to have the
320: (6)                  dangling dict to be the same as the personalization dict.
321: (4)                Returns
322: (4)                -------
323: (4)                pagerank : dictionary
324: (7)                   Dictionary of nodes with PageRank as value
325: (4)                Examples
326: (4)                --------
```

```
    >>> from networkx.algorithms.link_analysis.pagerank_alg import _pagerank_scipy
    >>> G = nx.DiGraph(nx.path_graph(4))
    >>> pr = _pagerank_scipy(G, alpha=0.9)
    Notes
    -----
    The eigenvector calculation uses power iteration with a SciPy
    sparse matrix representation.
    This implementation works with Multi(Di)Graphs. For multigraphs the
    weight between two nodes is set to be the sum of all edge weights
    between those nodes.
    See Also
    --------
    pagerank
    Raises
    ------
    PowerIterationFailedConvergence
        If the algorithm fails to converge to the specified tolerance
        within the specified number of iterations of the power iteration
        method.

17: (4)                 The equivalence classes, or blocks, consist of objects from `iterable`
18: (4)                 which are all equivalent. They are defined to be equivalent if the
19: (4)                 `relation` function returns `True` when passed any two objects from that
20: (4)                 class, and `False` otherwise. To define an equivalence relation the
21: (4)                 function must be reflexive, symmetric and transitive.
22: (4)                 Parameters
23: (4)                 ----------
24: (4)                 iterable : list, tuple, or set
25: (8)                     An iterable of elements/nodes.
26: (4)                 relation : function
27: (8)                     A Boolean-valued function that implements an equivalence relation
28: (8)                     (reflexive, symmetric, transitive binary relation) on the elements
29: (8)                     of `iterable` - it must take two elements and return `True` if
30: (8)                     they are related, or `False` if not.
31: (4)                 Returns
32: (4)                 -------
33: (4)                 set of frozensets
34: (8)                     A set of frozensets representing the partition induced by the
equivalence
35: (8)                     relation function `relation` on the elements of `iterable`. Each
```

```
        member set in the return set represents an equivalence class, or
        block, of the partition.
        Duplicate elements will be ignored so it makes the most sense for
        `iterable` to be a :class:`set`.
    Notes
    -----
    This function does not check that `relation` represents an equivalence
    relation. You can check that your equivalence classes provide a partition
    using `is_partition`.
    Examples
    --------
    Let `X` be the set of integers from `0` to `9`, and consider an equivalence
    relation `R` on `X` of congruence modulo `3`: this means that two integers
    `x` and `y` in `X` are equivalent under `R` if they leave the same
    remainder when divided by `3`, i.e. `(x - y) mod 3 = 0`.
    The equivalence classes of this relation are `{0, 3, 6, 9}`, `{1, 4, 7}`,
    `{2, 5, 8}`: `0`, `3`, `6`, `9` are all divisible by `3` and leave zero
    remainder; `1`, `4`, `7` leave remainder `1`; while `2`, `5` and `8` leave
    remainder `2`. We can see this by calling `equivalence_classes` with
    `X` and a function implementation of `R`.
    >>> X = set(range(10))
    >>> def mod3(x, y):
    ...     return (x - y) % 3 == 0
    >>> equivalence_classes(X, mod3)  # doctest: +SKIP
    {frozenset({1, 4, 7}), frozenset({8, 2, 5}), frozenset({0, 9, 3, 6})}
    """
    blocks = []
    for y in iterable:
        for block in blocks:
            x = arbitrary_element(block)
            if relation(x, y):
                block.append(y)
                break
        else:
            blocks.append([y])
    return {frozenset(block) for block in blocks}
@nx._dispatchable(edge_attrs="weight", returns_graph=True)
def quotient_graph(
    G,
    partition,
    edge_relation=None,
    node_data=None,
    edge_data=None,
    weight="weight",
    relabel=False,
    create_using=None,
):
    """Returns the quotient graph of `G` under the specified equivalence
    relation on nodes.
    Parameters
    ----------
    G : NetworkX graph
        The graph for which to return the quotient graph with the
        specified node relation.
    partition : function, or dict or list of lists, tuples or sets
        If a function, this function must represent an equivalence
        relation on the nodes of `G`. It must take two arguments *u*
        and *v* and return True exactly when *u* and *v* are in the
        same equivalence class. The equivalence classes form the nodes
        in the returned graph.
        If a dict of lists/tuples/sets, the keys can be any meaningful
        block labels, but the values must be the block lists/tuples/sets
        (one list/tuple/set per block), and the blocks must form a valid
        partition of the nodes of the graph. That is, each node must be
        in exactly one block of the partition.
        If a list of sets, the list must form a valid partition of
        the nodes of the graph. That is, each node must be in exactly
        one block of the partition.
```

```
    edge_relation : Boolean function with two arguments
        This function must represent an edge relation on the *blocks* of
        the `partition` of `G`. It must take two arguments, *B* and *C*,
        each one a set of nodes, and return True exactly when there should be
        an edge joining block *B* to block *C* in the returned graph.
        If `edge_relation` is not specified, it is assumed to be the
        following relation. Block *B* is related to block *C* if and
        only if some node in *B* is adjacent to some node in *C*,
        according to the edge set of `G`.
    node_data : function
        This function takes one argument, *B*, a set of nodes in `G`,
        and must return a dictionary representing the node data
        attributes to set on the node representing *B* in the quotient graph.
        If None, the following node attributes will be set:
        * 'graph', the subgraph of the graph `G` that this block
          represents,
        * 'nnodes', the number of nodes in this block,
        * 'nedges', the number of edges within this block,
        * 'density', the density of the subgraph of `G` that this
          block represents.
    edge_data : function
        This function takes two arguments, *B* and *C*, each one a set
        of nodes, and must return a dictionary representing the edge
        data attributes to set on the edge joining *B* and *C*, should
        there be an edge joining *B* and *C* in the quotient graph (if
        no such edge occurs in the quotient graph as determined by
        `edge_relation`, then the output of this function is ignored).
        If the quotient graph would be a multigraph, this function is
        not applied, since the edge data from each edge in the graph
        `G` appears in the edges of the quotient graph.
    weight : string or None, optional (default="weight")
        The name of an edge attribute that holds the numerical value
        used as a weight. If None then each edge has weight 1.
    relabel : bool
        If True, relabel the nodes of the quotient graph to be
        nonnegative integers. Otherwise, the nodes are identified with
        :class:`frozenset` instances representing the blocks given in
        `partition`.
    create_using : NetworkX graph constructor, optional (default=nx.Graph)
       Graph type to create. If graph instance, then cleared before populated.
    Returns
    -------
    NetworkX graph
        The quotient graph of `G` under the equivalence relation
        specified by `partition`. If the partition were given as a
        list of :class:`set` instances and `relabel` is False,
        each node will be a :class:`frozenset` corresponding to the same
        :class:`set`.
    Raises
    ------
    NetworkXException
        If the given partition is not a valid partition of the nodes of
        `G`.
    Examples
    --------
    The quotient graph of the complete bipartite graph under the "same
    neighbors" equivalence relation is `K_2`. Under this relation, two nodes
    are equivalent if they are not adjacent but have the same neighbor set.
    >>> G = nx.complete_bipartite_graph(2, 3)
    >>> same_neighbors = lambda u, v: (u not in G[v] and v not in G[u] and
G[u] == G[v])
    >>> Q = nx.quotient_graph(G, same_neighbors)
    >>> K2 = nx.complete_graph(2)
    >>> nx.is_isomorphic(Q, K2)
    True
    The quotient graph of a directed graph under the "same strongly connected
    component" equivalence relation is the condensation of the graph (see
    :func:`condensation`). This example comes from the Wikipedia article
    *`Strongly connected component`_*.
```

```
(4)                 >>> G = nx.DiGraph()

(4)                 >>> Q = nx.quotient_graph(G, same_component)
(4)                 >>> nx.is_isomorphic(C, Q)
(4)                 True
(4)                 Node identification can be represented as the quotient of a graph under
the
(4)                 equivalence relation that places the two nodes in one block and each other
(4)                 node in its own singleton block.
(4)                 >>> K24 = nx.complete_bipartite_graph(2, 4)
(4)                 >>> K34 = nx.complete_bipartite_graph(3, 4)
(4)                 >>> C = nx.contracted_nodes(K34, 1, 2)
(4)                 >>> nodes = {1, 2}
(4)                 >>> is_contracted = lambda u, v: u in nodes and v in nodes
(4)                 >>> Q = nx.quotient_graph(K34, is_contracted)
(4)                 >>> nx.is_isomorphic(Q, C)
(4)                 True
(4)                 >>> nx.is_isomorphic(Q, K24)
(4)                 True
(4)                 The blockmodeling technique described in [1]_ can be implemented as a
(4)                 quotient graph.
(4)                 >>> G = nx.path_graph(6)
(4)                 >>> partition = [{0, 1}, {2, 3}, {4, 5}]
(4)                 >>> M = nx.quotient_graph(G, partition, relabel=True)
(4)                 >>> list(M.edges())
(4)                 [(0, 1), (1, 2)]
(4)                 Here is the sample example but using partition as a dict of block sets.
(4)                 >>> G = nx.path_graph(6)
(4)                 >>> partition = {0: {0, 1}, 2: {2, 3}, 4: {4, 5}}
(4)                 >>> M = nx.quotient_graph(G, partition, relabel=True)
(4)                 >>> list(M.edges())
(4)                 [(0, 1), (1, 2)]
(4)                 Partitions can be represented in various ways:
(4)                 0. a list/tuple/set of block lists/tuples/sets
(4)                 1. a dict with block labels as keys and blocks lists/tuples/sets as values
(4)                 2. a dict with block lists/tuples/sets as keys and block labels as values
(4)                 3. a function from nodes in the original iterable to block labels
(4)                 4. an equivalence relation function on the target iterable
(4)                 As `quotient_graph` is designed to accept partitions represented as (0),
(1) or
(4)                 (4) only, the `equivalence_classes` function can be used to get the
partitions
(4)                 in the right form, in order to call `quotient_graph`.

(0)             )
(0)             def contracted_nodes(G, u, v, self_loops=True, copy=True):
(4)                 """Returns the graph that results from contracting `u` and `v`.
(4)                 Node contraction identifies the two nodes as a single node incident to any
(4)                 edge that was incident to the original two nodes.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(8)                     The graph whose nodes will be contracted.
(4)                 u, v : nodes
(8)                     Must be nodes in `G`.
(4)                 self_loops : Boolean
(8)                     If this is True, any edges joining `u` and `v` in `G` become
(8)                     self-loops on the new node in the returned graph.
(4)                 copy : Boolean
(8)                     If this is True (default True), make a copy of
(8)                     `G` and return that instead of directly changing `G`.
(4)                 Returns
(4)                 -------
(4)                 Networkx graph
(8)                     If Copy is True,
(8)                     A new graph object of the same type as `G` (leaving `G` unmodified)
(8)                     with `u` and `v` identified in a single node. The right node `v`
(8)                     will be merged into the node `u`, so only `u` will appear in the
(8)                     returned graph.
(8)                     If copy is False,
(8)                     Modifies `G` with `u` and `v` identified in a single node.
(8)                     The right node `v` will be merged into the node `u`, so
(8)                     only `u` will appear in the returned graph.
(4)                 Notes
(4)                 -----
(4)                 For multigraphs, the edge keys for the realigned edges may
(4)                 not be the same as the edge keys for the old edges. This is
(4)                 natural because edge keys are unique only within each pair of nodes.
(4)                 For non-multigraphs where `u` and `v` are adjacent to a third node
(4)                 `w`, the edge (`v`, `w`) will be contracted into the edge (`u`,
(4)                 `w`) with its attributes stored into a "contraction" attribute.
(4)                 This function is also available as `identified_nodes`.
(4)                 Examples
(4)                 --------
(4)                 Contracting two nonadjacent nodes of the cycle graph on four nodes `C_4`
(4)                 yields the path graph (ignoring parallel edges):
(4)                 >>> G = nx.cycle_graph(4)
```

```
    >>> M = nx.contracted_nodes(G, 1, 3)
    >>> P3 = nx.path_graph(3)
    >>> nx.is_isomorphic(M, P3)
    True
    >>> G = nx.MultiGraph(P3)
    >>> M = nx.contracted_nodes(G, 0, 2)
    >>> M.edges
    MultiEdgeView([(0, 1, 0), (0, 1, 1)])
    >>> G = nx.Graph([(1, 2), (2, 2)])
    >>> H = nx.contracted_nodes(G, 1, 2, self_loops=False)
    >>> list(H.nodes())
    [1]
    >>> list(H.edges())
    [(1, 1)]
    In a ``MultiDiGraph`` with a self loop, the in and out edges will
    be treated separately as edges, so while contracting a node which
    has a self loop the contraction will add multiple edges:
    >>> G = nx.MultiDiGraph([(1, 2), (2, 2)])
    >>> H = nx.contracted_nodes(G, 1, 2)
    >>> list(H.edges())  # edge 1->2, 2->2, 2<-2 from the original Graph G
    [(1, 1), (1, 1), (1, 1)]
    >>> H = nx.contracted_nodes(G, 1, 2, self_loops=False)
    >>> list(H.edges())  # edge 2->2, 2<-2 from the original Graph G
    [(1, 1), (1, 1)]

returns_graph=True)
7: (0)              def union_all(graphs, rename=()):
8: (4)                  """Returns the union of all graphs.
9: (4)                  The graphs must be disjoint, otherwise an exception is raised.
10: (4)                 Parameters
11: (4)                 ----------
12: (4)                 graphs : iterable
13: (7)                    Iterable of NetworkX graphs
14: (4)                 rename : iterable , optional
15: (7)                    Node names of graphs can be changed by specifying the tuple
16: (7)                    rename=('G-','H-') (for example).  Node "u" in G is then renamed
17: (7)                    "G-u" and "v" in H is renamed "H-v". Infinite generators (like
itertools.count)
18: (7)                    are also supported.
19: (4)                 Returns
20: (4)                 -------
21: (4)                 U : a graph with the same type as the first graph in list
22: (4)                 Raises
23: (4)                 ------
24: (4)                 ValueError
25: (7)                    If `graphs` is an empty list.
26: (4)                 NetworkXError
27: (8)                     In case of mixed type graphs, like MultiGraph and Graph, or directed
and undirected graphs.
28: (4)                 Notes
29: (4)                 -----
30: (4)                 For operating on mixed type graphs, they should be converted to the same
type.
31: (4)                 >>> G = nx.Graph()
32: (4)                 >>> H = nx.DiGraph()
33: (4)                 >>> GH = union_all([nx.DiGraph(G), H])
34: (4)                 To force a disjoint union with node relabeling, use
35: (4)                 disjoint_union_all(G,H) or convert_node_labels_to integers().
36: (4)                 Graph, edge, and node attributes are propagated to the union graph.
37: (4)                 If a graph attribute is present in multiple graphs, then the value
38: (4)                 from the last graph in the list with that attribute is used.
39: (4)                 Examples
40: (4)                 --------
41: (4)                 >>> G1 = nx.Graph([(1, 2), (2, 3)])
42: (4)                 >>> G2 = nx.Graph([(4, 5), (5, 6)])

58: (4)                 """Combine graphs G and H. The nodes are assumed to be unique (disjoint).
59: (4)                 This algorithm automatically relabels nodes to avoid name collisions.
```

```
60: (4)                 Parameters
61: (4)                 ----------
62: (4)                 G,H : graph
63: (7)                    A NetworkX graph
64: (4)                 Returns
65: (4)                 -------
66: (4)                 U : A union graph with the same type as G.
67: (4)                 See Also
68: (4)                 --------
69: (4)                 union
70: (4)                 compose
71: (4)                 :func:`~networkx.Graph.update`
72: (4)                 Notes
73: (4)                 -----
74: (4)                 A new graph is created, of the same class as G.  It is recommended
75: (4)                 that G and H be either both directed or both undirected.
76: (4)                 The nodes of G are relabeled 0 to len(G)-1, and the nodes of H are
77: (4)                 relabeled len(G) to len(G)+len(H)-1.
78: (4)                 Renumbering forces G and H to be disjoint, so no exception is ever raised
for a name collision.
79: (4)                 To preserve the check for common nodes, use union().
80: (4)                 Edge and node attributes are propagated from G and H to the union graph.
81: (4)                 Graph attributes are also propagated, but if they are present in both G
and H,
82: (4)                 then the value from H is used.
83: (4)                 To combine graphs that have common nodes, consider compose(G, H)
84: (4)                 or the method, Graph.update().
85: (4)                 Examples
86: (4)                 --------
87: (4)                 >>> G = nx.Graph([(0, 1), (0, 2), (1, 2)])

def compose(G, H):
    """Compose graph G with H by combining nodes and edges into a single
graph.
    The node sets and edges sets do not need to be disjoint.
    Composing preserves the attributes of nodes and edges.
    Attribute values from H take precedent over attribute values from G.
    Parameters
    ----------
    G, H : graph
       A NetworkX graph
    Returns
    -------
    C: A new graph with the same type as G
    See Also
    --------
    :func:`~networkx.Graph.update`
    union
    disjoint_union
    Notes
    -----
    It is recommended that G and H be either both directed or both undirected.
    For MultiGraphs, the edges are identified by incident nodes AND edge-key.
    This can cause surprises (i.e., edge `(1, 2)` may or may not be the same
    in two graphs) if you use MultiGraph without keeping track of edge keys.
    If combining the attributes of common nodes is not desired, consider
union(),
    which raises an exception for name collisions.
    Examples
    --------
    >>> G = nx.Graph([(0, 1), (0, 2)])
    >>> H = nx.Graph([(0, 1), (1, 2)])
    >>> R = nx.compose(G, H)
```

```
259: (4)                >>> R.nodes
260: (4)                NodeView((0, 1, 2))
261: (4)                >>> R.edges
262: (4)                EdgeView([(0, 1), (0, 2), (1, 2)])
263: (4)                By default, the attributes from `H` take precedent over attributes from
`G`.
264: (4)                If you prefer another way of combining attributes, you can update them
after the compose operation:
265: (4)                >>> G = nx.Graph([(0, 1, {"weight": 2.0}), (3, 0, {"weight": 100.0})])
266: (4)                >>> H = nx.Graph([(0, 1, {"weight": 10.0}), (1, 2, {"weight": -1.0})])
267: (4)                >>> nx.set_node_attributes(G, {0: "dark", 1: "light", 3: "black"},
name="color")
268: (4)                >>> nx.set_node_attributes(H, {0: "green", 1: "orange", 2: "yellow"},
name="color")
269: (4)                >>> GcomposeH = nx.compose(G, H)
270: (4)                Normally, color attribute values of nodes of GcomposeH come from H. We can
workaround this as follows:
271: (4)                >>> node_data = {
272: (4)                ...     n: G.nodes[n]["color"] + " " + H.nodes[n]["color"] for n in
G.nodes & H.nodes
273: (4)                ... }
274: (4)                >>> nx.set_node_attributes(GcomposeH, node_data, "color")
275: (4)                >>> print(GcomposeH.nodes[0]["color"])
276: (4)                dark green
277: (4)                >>> print(GcomposeH.nodes[3]["color"])
278: (4)                black
279: (4)                Similarly, we can update edge attributes after the compose operation in a
way we prefer:
280: (4)                >>> edge_data = {
281: (4)                ...     e: G.edges[e]["weight"] * H.edges[e]["weight"] for e in G.edges &
H.edges
282: (4)                ... }
283: (4)                >>> nx.set_edge_attributes(GcomposeH, edge_data, "weight")
284: (4)                >>> print(GcomposeH.edges[(0, 1)]["weight"])
285: (4)                20.0
286: (4)                >>> print(GcomposeH.edges[(3, 0)]["weight"])
287: (4)                100.0
288: (4)                """
289: (4)                return nx.compose_all([G, H])
290: (0)            @nx._dispatchable(graphs=_G_H, preserve_all_attrs=True, returns_graph=True)
291: (0)            def full_join(G, H, rename=(None, None)):
292: (4)                """Returns the full join of graphs G and H.
293: (4)                Full join is the union of G and H in which all edges between
294: (4)                G and H are added.
295: (4)                The node sets of G and H must be disjoint,
296: (4)                otherwise an exception is raised.
297: (4)                Parameters
298: (4)                ----------
299: (4)                G, H : graph
300: (7)                   A NetworkX graph
301: (4)                rename : tuple , default=(None, None)
302: (7)                   Node names of G and H can be changed by specifying the tuple
303: (7)                   rename=('G-','H-') (for example).  Node "u" in G is then renamed
304: (7)                   "G-u" and "v" in H is renamed "H-v".
305: (4)                Returns
306: (4)                -------
307: (4)                U : The full join graph with the same type as G.
308: (4)                Notes
309: (4)                -----
310: (4)                It is recommended that G and H be either both directed or both undirected.
311: (4)                If G is directed, then edges from G to H are added as well as from H to G.
312: (4)                Note that full_join() does not produce parallel edges for MultiGraphs.
313: (4)                The full join operation of graphs G and H is the same as getting
314: (4)                their complement, performing a disjoint union, and finally getting
315: (4)                the complement of the resulting graph.
316: (4)                Graph, edge, and node attributes are propagated from G and H
317: (4)                to the union graph.  If a graph attribute is present in both
318: (4)                G and H the value from H is used.

(4)     The tensor product $P$ of the graphs $G$ and $H$ has a node set that
(4)     is the Cartesian product of the node sets, $V(P)=V(G) \times V(H)$.
(4)     $P$ has an edge $((u,v), (x,y))$ if and only if $(u,x)$ is an edge in $G$
(4)     and $(v,y)$ is an edge in $H$.
(4)     Tensor product is sometimes also referred to as the categorical product,
(4)     direct product, cardinal product or conjunction.
(4)     Parameters
(4)     ----------
(4)     G, H: graphs
(5)      Networkx graphs.
(4)     Returns
(4)     -------
(4)     P: NetworkX graph
(5)      The tensor product of G and H. P will be a multi-graph if either G
(5)      or H is a multi-graph, will be a directed if G and H are directed,
(5)      and undirected if G and H are undirected.
(4)     Raises
(4)     ------
(4)     NetworkXError
(5)      If G and H are not both directed or both undirected.
(4)     Notes
(4)     -----
(4)     Node attributes in P are two-tuple of the G and H node attributes.
(4)     Missing attributes are assigned None.
(4)     Examples
(4)     --------
(4)     >>> G = nx.Graph()
(4)     >>> H = nx.Graph()
(4)     >>> G.add_node(0, a1=True)
(4)     >>> H.add_node("a", a2="Spam")
(4)     >>> P = nx.tensor_product(G, H)
(4)     >>> list(P)
(4)     [(0, 'a')]
(4)     Edge attributes and edge keys (for multigraphs) are also copied to the
(4)     new product graph

                Notes
                -----
                The *modular product* is defined in [1]_ and was first
                introduced as the *weak modular product*.
                The modular product reduces the problem of counting isomorphic subgraphs
                in `G` and `H` to the problem of counting cliques in M. The subgraphs of
                `G` and `H` that are induced by the nodes of a clique in M are
                isomorphic [2]_ [3]_.

cutoff=None):
10: (4)                 """Returns a list of nodes in a shortest path between source and target
11: (4)                 using the A* ("A-star") algorithm.
12: (4)                 There may be more than one shortest path.  This returns only one.
13: (4)                 Parameters
14: (4)                 ----------
15: (4)                 G : NetworkX graph
16: (4)                 source : node
17: (7)                    Starting node for path
18: (4)                 target : node
19: (7)                    Ending node for path
20: (4)                 heuristic : function
21: (7)                    A function to evaluate the estimate of the distance
22: (7)                    from the a node to the target.  The function takes
23: (7)                    two nodes arguments and must return a number.
24: (7)                    If the heuristic is inadmissible (if it might
25: (7)                    overestimate the cost of reaching the goal from a node),
26: (7)                    the result may not be a shortest path.
```

```
(7)                 The algorithm does not support updating heuristic
(7)                 values for the same node due to caching the first
(7)                 heuristic calculation per node.
(4)              weight : string or function
(7)                 If this is a string, then edge weights will be accessed via the
(7)                 edge attribute with this key (that is, the weight of the edge
(7)                 joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(7)                 such edge attribute exists, the weight of the edge is assumed to
(7)                 be one.
(7)                 If this is a function, the weight of an edge is the value
(7)                 returned by the function. The function must accept exactly three
(7)                 positional arguments: the two endpoints of an edge and the
(7)                 dictionary of edge attributes for that edge. The function must
(7)                 return a number or None to indicate a hidden edge.
(4)              cutoff : float, optional
(7)                 If this is provided, the search will be bounded to this value. I.e. if
(7)                 the evaluation function surpasses this value for a node n, the node
will not
(7)                 be expanded further and will be ignored. More formally, let h'(n) be
the
(7)                 heuristic function, and g(n) be the cost of reaching n from the source
node. Then,
(7)                 if g(n) + h'(n) > cutoff, the node will not be explored further.
(7)                 Note that if the heuristic is inadmissible, it is possible that paths
(7)                 are ignored even though they satisfy the cutoff.
(4)              Raises
(4)              ------
(4)              NetworkXNoPath
(8)                  If no path exists between source and target.
(4)              Examples
(4)              --------
(4)              >>> G = nx.path_graph(5)
(4)              >>> print(nx.astar_path(G, 0, 4))
(4)              [0, 1, 2, 3, 4]
(4)              >>> G = nx.grid_graph(dim=[3, 3])  # nodes are two-tuples (x,y)
(4)              >>> nx.set_edge_attributes(G, {e: e[1][0] * 2 for e in G.edges()}, "cost")

(4)              ...     return ((x1 - x2) ** 2 + (y1 - y2) ** 2) ** 0.5
(4)              >>> print(nx.astar_path(G, (0, 0), (2, 2), heuristic=dist, weight="cost"))
(4)              [(0, 0), (0, 1), (0, 2), (1, 2), (2, 2)]
(4)              Notes
(4)              -----
(4)              Edge weight attributes must be numerical.
(4)              Distances are calculated as sums of weighted edges traversed.
(4)              The weight function can be used to hide edges by returning None.
(4)              So ``weight = lambda u, v, d: 1 if d['color']=="red" else None``
(4)              will find the shortest red path.

33: (0)             def shortest_path(G, source=None, target=None, weight=None,
method="dijkstra"):
```

```
    """Compute shortest paths in the graph.
    Parameters
    ----------
    G : NetworkX graph
    source : node, optional
        Starting node for path. If not specified, compute shortest
        paths for each possible starting node.
    target : node, optional
        Ending node for path. If not specified, compute shortest
        paths to all possible nodes.
    weight : None, string or function, optional (default = None)
        If None, every edge has weight/distance/cost 1.
        If a string, use this edge attribute as the edge weight.
        Any edge attribute not present defaults to 1.
        If this is a function, the weight of an edge is the value
        returned by the function. The function must accept exactly
        three positional arguments: the two endpoints of an edge and
        the dictionary of edge attributes for that edge.
        The function must return a number.
    method : string, optional (default = 'dijkstra')
        The algorithm to use to compute the path.
        Supported options: 'dijkstra', 'bellman-ford'.
        Other inputs produce a ValueError.
        If `weight` is None, unweighted graph methods are used, and this
        suggestion is ignored.
    Returns
    -------
    path: list or dictionary
        All returned paths include both the source and target in the path.
        If the source and target are both specified, return a single list
        of nodes in a shortest path from the source to the target.
        If only the source is specified, return a dictionary keyed by
        targets with a list of nodes in a shortest path from the source
        to one of the targets.
        If only the target is specified, return a dictionary keyed by
        sources with a list of nodes in a shortest path from one of the
        sources to the target.
        If neither the source nor target are specified return a dictionary
        of dictionaries with path[source][target]=[list of nodes in path].
    Raises
    ------
    NodeNotFound
        If `source` is not in `G`.
    ValueError
        If `method` is not among the supported options.
    Examples
    --------
    >>> G = nx.path_graph(5)
    >>> print(nx.shortest_path(G, source=0, target=4))
    [0, 1, 2, 3, 4]
    >>> p = nx.shortest_path(G, source=0)  # target not specified
    >>> p[3]  # shortest path from source=0 to target=3
    [0, 1, 2, 3]
    >>> p = nx.shortest_path(G, target=4)  # source not specified
    >>> p[1]  # shortest path from source=1 to target=4
    [1, 2, 3, 4]
    >>> p = dict(nx.shortest_path(G))  # source, target not specified
    >>> p[2][4]  # shortest path from source=2 to target=4
    [2, 3, 4]
    Notes
    -----
    There may be more than one shortest path between a source and target.
    This returns only one of them.

method="dijkstra"):
157: (4)                """Compute shortest path lengths in the graph.
158: (4)                Parameters
159: (4)                ----------
160: (4)                G : NetworkX graph
161: (4)                source : node, optional
162: (8)                    Starting node for path.
163: (8)                    If not specified, compute shortest path lengths using all nodes as
164: (8)                    source nodes.
165: (4)                target : node, optional
```

```
(8)                 Ending node for path.
(8)                 If not specified, compute shortest path lengths using all nodes as
(8)                 target nodes.
(4)             weight : None, string or function, optional (default = None)
(8)                 If None, every edge has weight/distance/cost 1.
(8)                 If a string, use this edge attribute as the edge weight.
(8)                 Any edge attribute not present defaults to 1.
(8)                 If this is a function, the weight of an edge is the value
(8)                 returned by the function. The function must accept exactly
(8)                 three positional arguments: the two endpoints of an edge and
(8)                 the dictionary of edge attributes for that edge.
(8)                 The function must return a number.
(4)             method : string, optional (default = 'dijkstra')
(8)                 The algorithm to use to compute the path length.
(8)                 Supported options: 'dijkstra', 'bellman-ford'.
(8)                 Other inputs produce a ValueError.
(8)                 If `weight` is None, unweighted graph methods are used, and this
(8)                 suggestion is ignored.
(4)             Returns
(4)             -------
(4)             length: int or iterator

(8)                 the shortest path from the source to the target.
(8)                 If only the source is specified, return a dict keyed by target
(8)                 to the shortest path length from the source to that target.
(8)                 If only the target is specified, return a dict keyed by source
(8)                 to the shortest path length from that source to the target.
(8)                 If neither the source nor target are specified, return an iterator
(8)                 over (source, dictionary) where dictionary is keyed by target to
(8)                 shortest path length from source to that target.

(4)             Notes
(4)             -----
(4)             The length of the path is always 1 less than the number of nodes involved
(4)             in the path since the length measures the number of edges followed.
(4)             For digraphs this returns the shortest directed path length. To find path
(4)             lengths in the reverse direction use G.reverse(copy=False) first to flip
(4)             the edge orientation.

    Parameters
    ----------
    G : NetworkX graph
    target : node label
       Target node for path
    cutoff : integer, optional
        Depth to stop the search. Only paths of length <= cutoff are returned.
    Returns
    -------
    paths : dictionary
        Dictionary, keyed by target, of shortest paths.
    Examples
    --------
    >>> G = nx.path_graph(5, create_using=nx.DiGraph())
    >>> path = nx.single_target_shortest_path(G, 4)
    >>> path[0]
    [0, 1, 2, 3, 4]
    Notes
    -----
    The shortest path is not necessarily unique. So there can be multiple
    paths between the source and each target node, all of which have the
    same 'shortest' length. For each target node, this function returns
    only one of those paths.

39: (4)                 functions :func:`_dijkstra` and :func:`_bellman_ford_relaxation`.
40: (4)                 Parameters
41: (4)                 ----------
42: (4)                 G : NetworkX graph.
43: (4)                 weight : string or function
44: (8)                     If it is callable, `weight` itself is returned. If it is a string,
```

```
(8)                 it is assumed to be the name of the edge attribute that represents
(8)                 the weight of an edge. In that case, a function is returned that
(8)                 gets the edge weight according to the specified edge attribute.
(4)             Returns
(4)             -------
(4)             function
(8)                 This function returns a callable that accepts exactly three inputs:
(8)                 a node, an node adjacent to the first one, and the edge attribute
(8)                 dictionary for the eedge joining those nodes. That function returns
(8)                 a number representing the weight of an edge.
(4)             If `G` is a multigraph, and `weight` is not callable, the
(4)             minimum edge weight over all parallel edges is returned. If any edge
(4)             does not have an attribute with key `weight`, it is assumed to
(4)             have weight one.
(4)             """
(4)             if callable(weight):
(8)                 return weight
(4)             if G.is_multigraph():

(4)             """Returns the shortest weighted path from source to target in G.
(4)             Uses Dijkstra's Method to compute the shortest weighted path
(4)             between two nodes in a graph.
(4)             Parameters
(4)             ----------
(4)             G : NetworkX graph
(4)             source : node
(8)                 Starting node
(4)             target : node
(8)                 Ending node
(4)             weight : string or function
(8)                 If this is a string, then edge weights will be accessed via the
(8)                 edge attribute with this key (that is, the weight of the edge
(8)                 joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)                 such edge attribute exists, the weight of the edge is assumed to
(8)                 be one.
(8)                 If this is a function, the weight of an edge is the value
(8)                 returned by the function. The function must accept exactly three
(8)                 positional arguments: the two endpoints of an edge and the
(8)                 dictionary of edge attributes for that edge. The function must
(8)                 return a number or None to indicate a hidden edge.
(4)             Returns
(4)             -------
(4)             path : list
(8)                 List of nodes in a shortest path.
(4)             Raises
(4)             ------
(4)             NodeNotFound
(8)                 If `source` is not in `G`.
(4)             NetworkXNoPath
(8)                 If no path exists between source and target.
(4)             Examples
(4)             --------
(4)             >>> G = nx.path_graph(5)
(4)             >>> print(nx.dijkstra_path(G, 0, 4))
(4)             [0, 1, 2, 3, 4]
(4)             Find edges of shortest path in Multigraph
(4)             >>> G = nx.MultiDiGraph()
(4)             >>> G.add_weighted_edges_from([(1, 2, 0.75), (1, 2, 0.5), (2, 3, 0.5), (1,
3, 1.5)])

(4)      source nodes.
(4)      Compute the shortest path length between any of the source nodes and
(4)      all other reachable nodes for a weighted graph.
(4)      Parameters
(4)      ----------
(4)      G : NetworkX graph
(4)      sources : non-empty set of nodes
(8)          Starting nodes for paths. If this is just a set containing a
(8)          single node, then all paths computed by this function will start
(8)          from that node. If there are two or more nodes in the set, the
(8)          computed paths may begin from any one of the start nodes.
(4)      cutoff : integer or float, optional
(8)          Length (sum of edge weights) at which the search is stopped.
(8)          If cutoff is provided, only return paths with summed weight <= cutoff.
(4)      weight : string or function
(8)          If this is a string, then edge weights will be accessed via the
(8)          edge attribute with this key (that is, the weight of the edge
(8)          joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)          such edge attribute exists, the weight of the edge is assumed to
(8)          be one.
(8)          If this is a function, the weight of an edge is the value
(8)          returned by the function. The function must accept exactly three
(8)          positional arguments: the two endpoints of an edge and the
(8)          dictionary of edge attributes for that edge. The function must
(8)          return a number or None to indicate a hidden edge.
(4)      Returns
(4)      -------
(4)      length : dict
(8)          Dict keyed by node to shortest path length to nearest source.
(4)      Examples
(4)      --------
(4)      >>> G = nx.path_graph(5)
(4)      >>> length = nx.multi_source_dijkstra_path_length(G, {0, 4})
(4)      >>> for node in [0, 1, 2, 3, 4]:

weight="weight"):
    """Find shortest weighted paths and lengths from a given set of
    source nodes.
    Uses Dijkstra's algorithm to compute the shortest paths and lengths
    between one of the source nodes and the given `target`, or all other
    reachable nodes if not specified, for a weighted graph.
    Parameters
    ----------
    G : NetworkX graph
    sources : non-empty set of nodes
        Starting nodes for paths. If this is just a set containing a
        single node, then all paths computed by this function will start
        from that node. If there are two or more nodes in the set, the
        computed paths may begin from any one of the start nodes.
    target : node label, optional
        Ending node for path
    cutoff : integer or float, optional
        Length (sum of edge weights) at which the search is stopped.
        If cutoff is provided, only return paths with summed weight <= cutoff.
    weight : string or function
        If this is a string, then edge weights will be accessed via the
        edge attribute with this key (that is, the weight of the edge
        joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
        such edge attribute exists, the weight of the edge is assumed to
        be one.
        If this is a function, the weight of an edge is the value
        returned by the function. The function must accept exactly three
        positional arguments: the two endpoints of an edge and the
        dictionary of edge attributes for that edge. The function must
        return a number or None to indicate a hidden edge.
    Returns
    -------
    distance, path : pair of dictionaries, or numeric and list
        If target is None, returns a tuple of two dictionaries keyed by node.
        The first dictionary stores distance from one of the source nodes.
        The second stores the path from one of the sources to that node.
        If target is not None, returns a tuple of (distance, path) where
        distance is the distance from source to target and path is a list
        representing the path from source to target.
    Examples
    --------
    >>> G = nx.path_graph(5)
    >>> length, path = nx.multi_source_dijkstra(G, {0, 4})
    >>> for node in [0, 1, 2, 3, 4]:
    ...     print(f"{node}: {length[node]}")
    0: 0
    1: 1
    2: 2
    3: 1
    4: 0
    >>> path[1]
    [0, 1]
    >>> path[3]
    [4, 3]
    >>> length, path = nx.multi_source_dijkstra(G, {0, 4}, 1)
    >>> length
    1
    >>> path
    [0, 1]
    Notes
    -----
    Edge weight attributes must be numerical.
    Distances are calculated as sums of weighted edges traversed.
    The weight function can be used to hide edges by returning None.
    So ``weight = lambda u, v, d: 1 if d['color']=="red" else None``
    will find the shortest red path.
    Based on the Python cookbook recipe (119466) at
    https://code.activestate.com/recipes/119466/
    This algorithm is not guaranteed to work if edge weights
```

```

```
    G : NetworkX graph
    source : node label
        Starting node for path
    cutoff : integer or float, optional
        Length (sum of edge weights) at which the search is stopped.
        If cutoff is provided, only return paths with summed weight <= cutoff.
    weight : string or function
        If this is a string, then edge weights will be accessed via the
        edge attribute with this key (that is, the weight of the edge
        joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
        such edge attribute exists, the weight of the edge is assumed to
        be one.
        If this is a function, the weight of an edge is the value
        returned by the function. The function must accept exactly three
        positional arguments: the two endpoints of an edge and the
        dictionary of edge attributes for that edge. The function must
        return a number or None to indicate a hidden edge.
    Returns
    -------
    pred, distance : dictionaries
        Returns two dictionaries representing a list of predecessors
        of a node and the distance to each node.
    Raises
    ------
    NodeNotFound
        If `source` is not in `G`.
    Notes
    -----
    Edge weight attributes must be numerical.
    Distances are calculated as sums of weighted edges traversed.
    The list of predecessors contains more than one element only when
    there are more than one shortest paths to the key node.
    Examples
    --------
    >>> G = nx.path_graph(5, create_using=nx.DiGraph())
    >>> pred, dist = nx.dijkstra_predecessor_and_distance(G, 0)
    >>> sorted(pred.items())
    [(0, []), (1, [0]), (2, [1]), (3, [2]), (4, [3])]
    >>> sorted(dist.items())
    [(0, 0), (1, 1), (2, 2), (3, 3), (4, 4)]
    >>> pred, dist = nx.dijkstra_predecessor_and_distance(G, 0, 1)
    >>> sorted(pred.items())
    [(0, []), (1, [0])]
    >>> sorted(dist.items())
    [(0, 0), (1, 1)]
    """
    if source not in G:
        raise nx.NodeNotFound(f"Node {source} is not found in the graph")
    weight = _weight_function(G, weight)
    pred = {source: []}  # dictionary of predecessors
    return (pred, _dijkstra(G, source, weight, pred=pred, cutoff=cutoff))

def all_pairs_dijkstra(G, cutoff=None, weight="weight"):
    """Find shortest weighted paths and lengths between all nodes.
    Parameters
    ----------
    G : NetworkX graph
    cutoff : integer or float, optional
        Length (sum of edge weights) at which the search is stopped.
        If cutoff is provided, only return paths with summed weight <= cutoff.
    weight : string or function
        If this is a string, then edge weights will be accessed via the
        edge attribute with this key (that is, the weight of the edge
        joining `u` to `v` will be ``G.edge[u][v][weight]``). If no
        such edge attribute exists, the weight of the edge is assumed to
        be one.
        If this is a function, the weight of an edge is the value
        returned by the function. The function must accept exactly three
        positional arguments: the two endpoints of an edge and the
```

```
(8)                 dictionary of edge attributes for that edge. The function must
(8)                 return a number or None to indicate a hidden edge.
(4)             Yields
(4)             ------
(4)             (node, (distance, path)) : (node obj, (dict, dict))
(8)                 Each source node has two associated dicts. The first holds distance
(8)                 keyed by target and the second holds paths keyed by target.
(8)                 (See single_source_dijkstra for the source/target node terminology.)
(8)                 If desired you can apply `dict()` to this function to create a dict
(8)                 keyed by source node to the two dicts.
(4)             Examples
(4)             --------
(4)             >>> G = nx.path_graph(5)
(4)             >>> len_path = dict(nx.all_pairs_dijkstra(G))
(4)             >>> len_path[3][0][1]
(4)             2

925: (4)                """Compute shortest path lengths and predecessors on shortest paths
```

```
(4)                 in weighted graphs.
(4)                 The algorithm has a running time of $O(mn)$ where $n$ is the number of
(4)                 nodes and $m$ is the number of edges.  It is slower than Dijkstra but
(4)                 can handle negative edge weights.
(4)                 If a negative cycle is detected, you can use :func:`find_negative_cycle`
(4)                 to return the cycle and examine it. Shortest paths are not defined when
(4)                 a negative cycle exists because once reached, the path can cycle forever
(4)                 to build up arbitrarily low weights.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(8)                     The algorithm works for all types of graphs, including directed
(8)                     graphs and multigraphs.
(4)                 source: node label
(8)                     Starting node for path
(4)                 target : node label, optional
(8)                     Ending node for path
(4)                 weight : string or function
(8)                     If this is a string, then edge weights will be accessed via the
(8)                     edge attribute with this key (that is, the weight of the edge
(8)                     joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)                     such edge attribute exists, the weight of the edge is assumed to
(8)                     be one.
(8)                     If this is a function, the weight of an edge is the value
(8)                     returned by the function. The function must accept exactly three
(8)                     positional arguments: the two endpoints of an edge and the
(8)                     dictionary of edge attributes for that edge. The function must
(8)                     return a number.
(4)                 heuristic : bool
(8)                     Determines whether to use a heuristic to early detect negative
(8)                     cycles at a hopefully negligible cost.
(4)                 Returns
(4)                 -------
(4)                 pred, dist : dictionaries
(8)                     Returns two dictionaries keyed by node to predecessor in the
(8)                     path and to the distance from the source respectively.
(4)                 Raises
(4)                 ------
(4)                 NodeNotFound
(8)                     If `source` is not in `G`.
(4)                 NetworkXUnbounded
(8)                     If the (di)graph contains a negative (di)cycle, the
(8)                     algorithm raises an exception to indicate the presence of the
(8)                     negative (di)cycle.  Note: any negative weight edge in an
(8)                     undirected graph is a negative cycle.
(4)                 Examples
(4)                 --------
(4)                 >>> G = nx.path_graph(5, create_using=nx.DiGraph())

    reachable nodes for a weighted graph.
    Parameters
    ----------
    G : NetworkX graph
    source : node label
        Starting node for path
    weight : string or function (default="weight")
        If this is a string, then edge weights will be accessed via the
        edge attribute with this key (that is, the weight of the edge
        joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
        such edge attribute exists, the weight of the edge is assumed to
        be one.
        If this is a function, the weight of an edge is the value
        returned by the function. The function must accept exactly three
        positional arguments: the two endpoints of an edge and the
        dictionary of edge attributes for that edge. The function must
        return a number.
    Returns
    -------
    length : dictionary
        Dictionary of shortest path length keyed by target
    Raises
    ------
    NodeNotFound
        If `source` is not in `G`.
    Examples
    --------
    >>> G = nx.path_graph(5)
    >>> length = nx.single_source_bellman_ford_path_length(G, 0)
    >>> length[4]
    4
    >>> for node in [0, 1, 2, 3, 4]:

    """Compute shortest path lengths and predecessors on shortest paths
    in weighted graphs.
    The algorithm has a running time of $O(mn)$ where $n$ is the number of
    nodes and $m$ is the number of edges.  It is slower than Dijkstra but
    can handle negative edge weights.
    Parameters
    ----------
    G : NetworkX graph
        The algorithm works for all types of graphs, including directed
        graphs and multigraphs.
    source: node label
        Starting node for path
    weight : string or function
        If this is a string, then edge weights will be accessed via the
        edge attribute with this key (that is, the weight of the edge
        joining `u` to `v` will be ``G.edges[u, v][weight]``). If no

        positional arguments: the two endpoints of an edge and the
        dictionary of edge attributes for that edge. The function must
        return a number.
    Returns
    -------
    pred, dist : dictionaries
        Returns two dictionaries keyed by node to predecessor in the
        path and to the distance from the source respectively.
    Raises
    ------
    NodeNotFound
        If `source` is not in `G`.
    NetworkXUnbounded
        If the (di)graph contains a negative (di)cycle, the
        algorithm raises an exception to indicate the presence of the
        negative (di)cycle.  Note: any negative weight edge in an
        undirected graph is a negative cycle.
        As of NetworkX v3.2, a zero weight cycle is no longer
        incorrectly reported as a negative weight cycle.
    Examples
    --------
    >>> G = nx.path_graph(5, create_using=nx.DiGraph())
    >>> pred, dist = nx.goldberg_radzik(G, 0)
    >>> sorted(pred.items())

(0)         def negative_edge_cycle(G, weight="weight", heuristic=True):
(4)             """Returns True if there exists a negative edge cycle anywhere in G.
(4)             Parameters
(4)             ----------
(4)             G : NetworkX graph
(4)             weight : string or function
(8)                 If this is a string, then edge weights will be accessed via the
(8)                 edge attribute with this key (that is, the weight of the edge
(8)                 joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)                 such edge attribute exists, the weight of the edge is assumed to
(8)                 be one.

(8)                 returned by the function. The function must accept exactly three
(8)                 positional arguments: the two endpoints of an edge and the
(8)                 dictionary of edge attributes for that edge. The function must
(8)                 return a number.
(4)             heuristic : bool
(8)                 Determines whether to use a heuristic to early detect negative
(8)                 cycles at a negligible cost. In case of graphs with a negative cycle,
(8)                 the performance of detection increases by at least an order of
magnitude.
(4)             Returns
(4)             -------
(4)             negative_cycle : bool
(8)                 True if a negative edge cycle exists, otherwise False.
(4)             Examples
(4)             --------
(4)             >>> G = nx.cycle_graph(5, create_using=nx.DiGraph())
(4)             >>> print(nx.negative_edge_cycle(G))
(4)             False
(4)             >>> G[1][2]["weight"] = -7
(4)             >>> print(nx.negative_edge_cycle(G))
(4)             True
(4)             Notes
(4)             -----
(4)             Edge weight attributes must be numerical.
(4)             Distances are calculated as sums of weighted edges traversed.
(4)             This algorithm uses bellman_ford_predecessor_and_distance() but finds
(4)             negative cycles on any component by first adding a new node connected to
(4)             every node, and starting bellman_ford_predecessor_and_distance on that
(4)             node.  It then removes that extra node.
(4)             """

(4)             G : NetworkX graph
(4)             source : node
(8)                 Starting node.
(4)             target : node
(8)                 Ending node.
(4)             weight : string or function
(8)                 If this is a string, then edge weights will be accessed via the
(8)                 edge attribute with this key (that is, the weight of the edge
(8)                 joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)                 such edge attribute exists, the weight of the edge is assumed to
(8)                 be one.
(8)                 If this is a function, the weight of an edge is the value
(8)                 returned by the function. The function must accept exactly three
(8)                 positional arguments: the two endpoints of an edge and the
(8)                 dictionary of edge attributes for that edge. The function must
(8)                 return a number or None to indicate a hidden edge.
(4)             Returns
(4)             -------
(4)             length, path : number and list
(8)                 length is the distance from source to target.
(8)                 path is a list of nodes on a path from source to target.
(4)             Raises
(4)             ------
(4)             NodeNotFound
(8)                 If either `source` or `target` is not in `G`.
(4)             NetworkXNoPath
(8)                 If no path exists between source and target.
(4)             Examples
(4)             --------
(4)             >>> G = nx.path_graph(5)
(4)             >>> length, path = nx.bidirectional_dijkstra(G, 0, 4)
(4)             >>> print(length)
(4)             4
(4)             >>> print(path)
(4)             [0, 1, 2, 3, 4]
(4)             Notes
(4)             -----
(4)             Edge weight attributes must be numerical.
(4)             Distances are calculated as sums of weighted edges traversed.
(4)             The weight function can be used to hide edges by returning None.
(4)             So ``weight = lambda u, v, d: 1 if d['color']=="red" else None``
(4)             will find the shortest red path.
(4)             In practice  bidirectional Dijkstra is much more than twice as fast as
(4)             ordinary Dijkstra.
(4)             Ordinary Dijkstra expands nodes in a sphere-like manner from the
(4)             source. The radius of this sphere will eventually be the length
(4)             of the shortest path. Bidirectional Dijkstra will expand nodes
(4)             from both the source and the target, making two spheres of half
(4)             this radius. Volume of the first sphere is `\pi*r*r` while the
(4)             others are `2*\pi*r/2*r/2`, making up half the volume.
(4)             This algorithm is not guaranteed to work if edge weights
(4)             are negative or are floating point numbers
(4)             (overflows and roundoff errors can cause problems).

(0)             def johnson(G, weight="weight"):
(4)                 r"""Uses Johnson's Algorithm to compute shortest paths.
(4)                 Johnson's Algorithm finds a shortest path between each pair of
(4)                 nodes in a weighted graph even if negative weights are present.
(4)                 Parameters
(4)                 ----------
(4)                 G : NetworkX graph
(4)                 weight : string or function
(8)                     If this is a string, then edge weights will be accessed via the
(8)                     edge attribute with this key (that is, the weight of the edge
(8)                     joining `u` to `v` will be ``G.edges[u, v][weight]``). If no
(8)                     such edge attribute exists, the weight of the edge is assumed to
(8)                     be one.
```

```
1945: (8)                   If this is a function, the weight of an edge is the value
1946: (8)                   returned by the function. The function must accept exactly three
1947: (8)                   positional arguments: the two endpoints of an edge and the
1948: (8)                   dictionary of edge attributes for that edge. The function must
1949: (8)                   return a number.
1950: (4)               Returns
1951: (4)               -------
1952: (4)               distance : dictionary
1953: (8)                   Dictionary, keyed by source and target, of shortest paths.
1954: (4)               Examples
1955: (4)               --------
1956: (4)               >>> graph = nx.DiGraph()
1957: (4)               >>> graph.add_weighted_edges_from(
1958: (4)               ...     [("0", "3", 3), ("0", "1", -5), ("0", "2", 2), ("1", "2", 4),
("2", "3", 1)]
1959: (4)               ... )
1960: (4)               >>> paths = nx.johnson(graph, weight="weight")
1961: (4)               >>> paths["0"]["2"]
1962: (4)               ['0', '1', '2']
1963: (4)               Notes
1964: (4)               -----
1965: (4)               Johnson's algorithm is suitable even for graphs with negative weights. It
1966: (4)               works by using the Bellman-Ford algorithm to compute a transformation of
1967: (4)               the input graph that removes all negative weights, allowing Dijkstra's
1968: (4)               algorithm to be used on the transformed graph.
1969: (4)               The time complexity of this algorithm is $O(n^2 \log n + n m)$,
1970: (4)               where $n$ is the number of nodes and $m$ the number of edges in the
1971: (4)               graph. For dense graphs, this may be faster than the Floyd-Warshall
1972: (4)               algorithm.
