## File 140 - ufuncs.py:

```

1: (0)         """
2: (0)         =====
3: (0)         Universal Functions
4: (0)         =====
5: (0)         Ufuncs are, generally speaking, mathematical functions or operations that are
6: (0)         applied element-by-element to the contents of an array. That is, the result
7: (0)         in each output array element only depends on the value in the corresponding
8: (0)         input array (or arrays) and on no other array elements. NumPy comes with a
9: (0)         large suite of ufuncs, and scipy extends that suite substantially. The
simplest
10: (0)        example is the addition operator: :::
11: (1)        >>> np.array([0,2,3,4]) + np.array([1,1,-1,2])
12: (1)        array([1, 3, 2, 6])
13: (0)        The ufunc module lists all the available ufuncs in numpy. Documentation on
14: (0)        the specific ufuncs may be found in those modules. This documentation is
15: (0)        intended to address the more general aspects of ufuncs common to most of
16: (0)        them. All of the ufuncs that make use of Python operators (e.g., +, -, etc.)
17: (0)        have equivalent functions defined (e.g. add() for +)
18: (0)        Type coercion
19: (0)        =====
20: (0)        What happens when a binary operator (e.g., +, -, \*, /, etc) deals with arrays
of
21: (0)        two different types? What is the type of the result? Typically, the result is
22: (0)        the higher of the two types. For example: :::
23: (1)        float32 + float64 -> float64
24: (1)        int8 + int32 -> int32
25: (1)        int16 + float32 -> float32
26: (1)        float32 + complex64 -> complex64
27: (0)        There are some less obvious cases generally involving mixes of types
28: (0)        (e.g. uints, ints and floats) where equal bit sizes for each are not
29: (0)        capable of saving all the information in a different type of equivalent
30: (0)        bit size. Some examples are int32 vs float32 or uint32 vs int32.
31: (0)        Generally, the result is the higher type of larger size than both
32: (0)        (if available). So: :::
33: (1)        int32 + float32 -> float64
34: (1)        uint32 + int32 -> int64
35: (0)        Finally, the type coercion behavior when expressions involve Python
36: (0)        scalars is different than that seen for arrays. Since Python has a
37: (0)        limited number of types, combining a Python int with a dtype=np.int8
38: (0)        array does not coerce to the higher type but instead, the type of the
39: (0)        array prevails. So the rules for Python scalars combined with arrays is
40: (0)        that the result will be that of the array equivalent the Python scalar
41: (0)        if the Python scalar is of a higher 'kind' than the array (e.g., float
42: (0)        vs. int), otherwise the resultant type will be that of the array.
43: (0)        For example: :::
44: (2)        Python int + int8 -> int8
45: (2)        Python float + int8 -> float64
46: (0)        ufunc methods
47: (0)        =====
48: (0)        Binary ufuncs support 4 methods.
49: (0)        **.reduce(arr)** applies the binary operator to elements of the array in
50: (2)        sequence. For example: :::
51: (1)        >>> np.add.reduce(np.arange(10)) # adds all elements of array
52: (1)        45
53: (0)        For multidimensional arrays, the first dimension is reduced by default: :::
54: (1)        >>> np.add.reduce(np.arange(10).reshape(2,5))
55: (5)        array([ 5,  7,  9, 11, 13])
56: (0)        The axis keyword can be used to specify different axes to reduce: :::
57: (1)        >>> np.add.reduce(np.arange(10).reshape(2,5),axis=1)
```

SANJOYNATHQHENOMENOLOGYGEOMETRIFYINGTRIGONOMETRY\_combined\_python\_files\_20\_chars.txt

```

58: (1) array([10, 35])
59: (0) **.accumulate(arr)** applies the binary operator and generates an
60: (0) equivalently shaped array that includes the accumulated amount for each
61: (0) element of the array. A couple examples: :::
62: (1) >>> np.add.accumulate(np.arange(10))
63: (1) array([ 0,  1,  3,  6, 10, 15, 21, 28, 36, 45])
64: (1) >>> np.multiply.accumulate(np.arange(1,9))
65: (1) array([ 1,   2,   6,  24, 120, 720, 5040, 40320])
66: (0) The behavior for multidimensional arrays is the same as for .reduce(), as is the use of the axis keyword).
67: (0)
68: (0) **.reduceat(arr,indices)** allows one to apply reduce to selected parts
69: (2) of an array. It is a difficult method to understand. See the documentation
70: (2) at:
71: (0) **.outer(arr1,arr2)** generates an outer operation on the two arrays arr1 and
72: (2) arr2. It will work on multidimensional arrays (the shape of the result is
73: (2) the concatenation of the two input shapes.:::
74: (1) >>> np.multiply.outer(np.arange(3),np.arange(4))
75: (1) array([[0, 0, 0, 0],
76: (8)         [0, 1, 2, 3],
77: (8)         [0, 2, 4, 6]])
78: (0) Output arguments
79: (0) =====
80: (0) All ufuncs accept an optional output array. The array must be of the expected
81: (0) output shape. Beware that if the type of the output array is of a different
82: (0) (and lower) type than the output result, the results may be silently truncated
83: (0) or otherwise corrupted in the downcast to the lower type. This usage is useful
84: (0) when one wants to avoid creating large temporary arrays and instead allows one
85: (0) to reuse the same array memory repeatedly (at the expense of not being able to
86: (0) use more convenient operator notation in expressions). Note that when the
87: (0) output argument is used, the ufunc still returns a reference to the result.
88: (1) >>> x = np.arange(2)
89: (1) >>> np.add(np.arange(2),np.arange(2.),x)
90: (1) array([0, 2])
91: (1) >>> x
92: (1) array([0, 2])
93: (0) and & or as ufuncs
94: (0) =====
95: (0) Invariably people try to use the python 'and' and 'or' as logical operators
96: (0) (and quite understandably). But these operators do not behave as normal
97: (0) operators since Python treats these quite differently. They cannot be
98: (0) overloaded with array equivalents. Thus using 'and' or 'or' with an array
99: (0) results in an error. There are two alternatives:
100: (1) 1) use the ufunc functions logical_and() and logical_or().
101: (1) 2) use the bitwise operators & and \|. The drawback of these is that if
102: (4) the arguments to these operators are not boolean arrays, the result is
103: (4) likely incorrect. On the other hand, most usages of logical_and and
104: (4) logical_or are with boolean arrays. As long as one is careful, this is
105: (4) a convenient way to apply these operators.
106: (0)

681: (4)   Update the Fortran-to-C type mapping dictionary with new mappings and

```

```

682: (4) return a list of successfully mapped C types.
683: (4) This function integrates a new mapping dictionary into an existing
684: (4) Fortran-to-C type mapping dictionary. It ensures that all keys are in
685: (4) lowercase and validates new entries against a given C-to-Python mapping
686: (4) dictionary. Redefinitions and invalid entries are reported with a warning.
687: (4) Parameters
688: (4) -----
689: (4) f2cmap_all : dict
690: (8) The existing Fortran-to-C type mapping dictionary that will be
updated.
691: (8) It should be a dictionary of dictionaries where the main keys
represent
692: (8) Fortran types and the nested dictionaries map Fortran type specifiers
693: (8) to corresponding C types.
694: (4) new_map : dict
695: (8) A dictionary containing new type mappings to be added to `f2cmap_all`.
696: (8) The structure should be similar to `f2cmap_all`, with keys
representing
697: (8) Fortran types and values being dictionaries of type specifiers and
their
698: (8) C type equivalents.
699: (4) c2py_map : dict
700: (8) A dictionary used for validating the C types in `new_map`. It maps C
701: (8) types to corresponding Python types and is used to ensure that the C
702: (8) types specified in `new_map` are valid.
703: (4) verbose : boolean
704: (8) A flag used to provide information about the types mapped
Returns
705: (4) -----
706: (4) tuple of (dict, list)
707: (4) The updated Fortran-to-C type mapping dictionary and a list of
708: (8) successfully mapped C types.
